PREFACE

In preparing new material and revising existing material for this Fifth tion, the same guiding principles have been followed as in the First ition in 1933. Throughout, the endeavor has been to create a compre-nsive working manual and to compile in a single volume concise formation on each of the branches of communication engineering.

science with as many variable parameters as electronics, the only daries are those of the imagination of the scientists and engineers. ach decade brings forth totally new concepts and new tools. The riod from 1950, when the Fourth Edition was published, to 1959 has n no exception. There has been no stagnation; no settling down; no ange from dynamic progress.

This edition, therefore, contains much that appeared only in brief form, at all, in the previous editions. All chapters have been brought up to ate; seven of them have been totally rewritten In addition seven apters are totally new And because there is no longer much difference etween the tools employed by telegraph and telephone engineers and ose used by radio men, this volume now has chapters devoted to wire-ided communication. Thus this Fifth Edition becomes a "com-unications" handbook and not one concerned solely with space-guided formation transmission. The original name, however, has been tained

While there is much of what may be called fundamental background in is book, the emphasis has been on working practice rather than theory general concept of the purpose of a "handbook."

The engineer will find here many man-hours of effort compiled in the rm of tables and curves or converted into concise English by the engi-rs, physicists, and teachers who have aided the editor in preparing this w edition To these authors the editor wishes to express his very great

CONTENTS

CHAPTER 1

BASIS OF RADIO-COMMUNICATION ENGINEERING

By Beverly Dudley[1]

1. Introduction. Radio-communication engineering may be defined as the art and science by which materials and natural phenomena are utilized in the design, construction, and operation of apparatus to convey information or to effect remote control between two or more points through the use of electromagnetic waves.

Man has no knowledge of, and no contact with, his environment, except as through his senses. Therefore, if man is to benefit from radio-communication engineering, information must be conveyed to him by variation of forms of energy that will stimulate or affect one or more of his senses. Moreover, if information is to be conveyed, some prearranged and generally understood sequence of symbols or signals—some form of language, however rudimentary, and generally expressed as a single-valued function of time—must be developed and understood by the parties involved.

Design and construction of instrumentalities for effective radio communication demand the proper use of material substances and that the forces of electricity and magnetism be manipulated to produce electromagnetic waves, modified to contain or represent the information to be conveyed, simultaneously possessing characteristics to enable their passage through the transmission medium. Since there appears to be no economical or practical possibility that man can control the characteristics of the earth's atmosphere, successful radio communication (especially that conducted over long distances) requires that the electromagnetic-propagation characteristics of the earth's atmosphere be observed and studied so that natural phenomena may be utilized most advantageously.

Modern radio communication therefore rests upon the five fundamental bases:

1. The physical, physiological, and psychological foundations of man's sense perceptions, especially those of seeing and hearing
2. The analysis, formulation, and manipulation of intelligence expressed as a single-valued function of time in a form suitable for transmission between two or more points
3. The fundamental structure of matter, and particularly the manner in which the properties of material substances depend upon, or are influenced by, the composition and arrangement of elementary particles of which they are composed
4. The fundamentals of those branches of physics (primarily electromagnetism) by which electromagnetic waves are generated, modulated, launched at a transmitter, and intercepted at a receiving point where the intelligence imparted in the modulation process is extracted by a process of demodulation or detection
5. The propagation characteristics of the medium through which the electromagnetic waves travel from the transmitting end to the receiving point

Because the scientist and engineer are concerned with quantitative relationships between the numerous entities and variables encountered in the five fundamental bases enumerated above, mathematics, "the science of treating of the exact relations existing between quantities or magnitudes and operations, and of methods by which, in accordance with these relations, quantities sought are deducible from others known or supposed," may be regarded as a sixth fundamental basis of radio engineering. In addition to all the elementary branches of mathematics, radio engineers may be called upon to make use of such intermediate and advanced mathematical subjects as the

[1] Massachusetts Institute of Technology.

differential and integral calculus, ordinary and partial differential equations, vector analysis, functions of a real and complex variable, statistics and probability theory, symbolic and operational methods such as Fourier and Laplace transformations, the calculus of variation, and generalized harmonic analysis.

No single book can hope to provide adequate presentation of all the data that a radio engineer may need in the pursuit of his profession, and this first chapter, concerned primarily with developing an outline of the five fundamental bases enumerated above, will err from the standpoint of completeness because of the necessity for brevity and conciseness. Numerous topics must be omitted completely, and others have not yet reached the point where they lend themselves to definitive and concise handbook treatment. Fuller treatment may be found in the many references listed.

PRINCIPLES OF ELECTRICAL COMMUNICATION

2. Signals. Communication is carried on by the successive selection and arrangement of prearranged or understood symbols. The proper selection and sequential arrangement of such symbols or signals at one part of the communication system provide the means by which intelligence (that cannot be completely predicted at some other point of the system) is conveyed, in accordance with the meanings attached to, or the information represented by, the symbols. Since a sequence of symbols is required to convey information, one of the important characteristic properties of intelligence is that it can be expressed as a single-valued function of time.

Each separate and different symbol must vary in some respect from all others, and it must also convey a separate and distinct meaning. Each different symbol must be unique; it must represent or express a unique meaning, and it must be expressible as a unique function of time. Hence a group of different signals or symbols represents a variety of unique time functions; it also represents a variety of unique frequency functions, since time and frequency are inversely related. A group of signals or symbols representing intelligence may therefore be represented by a band of signal frequencies.

These statements are valid for all kinds of communication systems, no matter what means may be employed to convey intelligence between two or more points. These are important results for the engineer, for they make possible the effective and economical transmission of information by electrical means.

Another important characteristic of intelligence or information is its unpredictability. *No new information is conveyed by any operation that is completely predictable.* This point, which has received considerable attention since the Second World War, is one of the cornerstones of modern communication or information theory.

3. Speed of Electrical Communication. The speed with which signals may be transmitted from one point and reproduced at another distant point is of great practical importance. Because electromagnetic phenomena may be propagated between two points with speeds that can, and usually do, approach the velocity of light (186,300 miles per second), electrical methods of communication have replaced, almost entirely, other means of communication over appreciable distances.

4. The Carrier and the Transmission Medium. For satisfactory communication to be effected between two or more points by means of electrical energy, a transmission path must exist between those points. When a suitable path is provided, electrical energy then serves as the vehicle, or *carrier*, by which communication may be effected. In wire-communication systems, electric current or voltage serves as the carrier. In ordinary local telephone or telegraph systems, the carrier current may be unidirectional and unvarying; in other words, it is a direct current of zero frequency. In more complex systems, the carrier current may oscillate periodically and is then characterized by the frequency of oscillation. In radio systems, the carrier wave is comprised of periodic oscillations of the electromagnetic field which determine the frequency of the carrier wave. Electromagnetic waves used as the carrier in radio systems can be produced conveniently and economically only at frequencies of 10,000 cps or more, and usually frequencies very much greater than these are employed.

Of itself, steady-state electrical energy in the appropriate form for passage through

the transmission medium is insufficient to permit significant communication to take place. Electrical energy does not produce sensory perceptions directly. But even if this possibility did exist, it would still be necessary to impart to the carrier the intelligence contained in, or represented by, the signal, for the unmodulated carrier alone contains only trivial information.

5. Electrosensory Transducers. Because electrical energy does not directly produce sensory perceptions or conversely, all systems of electrical communication require: (1) some means for converting sense perceptions into electrical energy at one point and (2) some means at a receiving point for reconverting the received electrical energy into a form capable of stimulating or exciting one or more of the senses. Thus electrosensory transducers—or equivalent substitutes—are required at those points at which intelligence is to be imparted to or extracted from the communication system. These transducers are almost always—but not necessarily—complementarily related, so that the reproduced form of intelligence is of the same kind as the original form of intelligence.

By an electrosensory transducer at the transmitter, sense-perceptory energy corresponding to the selection and sequential arrangement of symbols and representing the intelligence to be conveyed is converted into variations of electrical energy as a single-valued function of time. Such energy conversion occurs at the signal frequency, or band of frequencies, and represents the signal information. Hence the signal variations of energy of the system must be related to, or must correspond to, the frequency band represented by the selection and sequential arrangement of symbols; this must also be true at each and every point of the transmission system.

6. Functions of Signal and Carrier. If the carrier is to convey information through the transmission medium, some property of the carrier must be modulated or varied in accordance with the signal. In a modulated carrier, the carrier wave enables the electrical energy to be passed through the transmission medium, whereas the modulation at signal frequencies imparts to the carrier the information to be communicated.

When the modulated carrier wave has passed through the transmission medium and is intercepted at a receiving point, it is passed through a suitable demodulating device, or detector, so that the signal frequencies may be separated from the carrier. The signal frequencies then actuate an electrosensory transducer so that the signal information is reconverted into an appropriate sequence and arrangement of sense-perceptory symbols. The reproduced symbols should be sufficiently like those initially impressed upon the system that they will be recognized for their intended meaning.

7. Channel Selection. For most kinds of radio systems, the carrier wave is generated as a harmonically varying time function of voltage, current, or field intensity. Thus, the instantaneous value of the carrier may be $i = I_c \cos(\omega t + \phi)$, where I_c is the maximum value of the harmonic variation, $\omega = 2\pi f$ is the angular frequency in radians per second if f is the cyclic frequency in cycles per second (cps), and ϕ is the phase angle which determines the value of the function for time $t = 0$. For such a wave, the carrier is characterized by a single, constant, and fixed frequency, $f = \omega/2\pi$ cps. When a constant-frequency carrier is modulated by a band of signal frequencies, the carrier frequency is no longer constant and fixed but is broadened into a band of frequencies, the spectrum of the modulated wave usually extending above and below the carrier frequency by an amount depending upon the band of signal frequencies with which the carrier is modulated. The frequency spectrum occupied by a carrier and its signal side bands is commonly called a *communication channel.*

In the process of modulation, information is shifted from the band of signal frequencies to a higher (occasionally to a lower) part of the frequency spectrum adjacent to the carrier frequency. The modulated wave has information-bearing side bands with essentially the same propagation characteristics as the carrier wave. Through the use of equipment of such spectral selectivity as will accept the carrier frequency and the side-band frequencies, the information contained in the band of signal frequencies becomes available at the receiving point, although shifted in the spectrum.

More than one modulated carrier, each of which contains a different message or

signal, can be transmitted simultaneously through the same transmission medium. Provided each carrier wave with its associated side bands occupies a frequency channel or a portion of the frequency spectrum devoid of frequency components of some other modulated carrier wave (with its associated side bands), it is possible to separate the modulated carriers on a frequency-selective basis, and to obtain the signal information imparted to each carrier, free from interference from the other modulated carriers in the medium.

The success of such channel-selection techniques usually requires that each modulated carrier operate within its assigned channel or frequency spectrum. For the most part, the frequencies of each separate modulated carrier must lie within the assigned frequency channel, the frequencies of adjacent channels should not overlap, and the frequency selectivity of the receiving apparatus must be such as to accept substantially all frequency components of one channel and exclude the frequency components of neighboring channels.

8. General Problem of Electrical Communication. The general problem is to make possible, as well as economically feasible, all the essential operations of the communication system. Moreover, the system as a whole must be so organized and correlated that the sense perceptions reproduced at the receiving points are essentially the same as those initiated at, and impressed upon, the system at the transmitting point. The means by which the various individual steps are accomplished depend upon: (1) the type or mode of communication, (2) the kind or type of information to be communicated, and (3) the area or location of the receiving points relative to that of the transmitting point or points.

9. Fundamental Steps in Electrical Communication Systems. No matter how simple or how complex the communication system may be, the essential steps may be divided into four distinct operations:

1. The *formulation* of intelligence—expressed by means of signals or symbols—in a manner capable of producing subjective sensations or of effecting remote-control operations. This step is common to all communication systems, whether electrical or not. In radio systems, the most representative types of signals are the dot-dash signals of the Morse code in telegraphy, voice or music signals in telephony, and the scanning signals for picture transmission.
2. The *conversion* of the intelligence into electrical energy of such properties as to be capable of conveying information through the selected transmission medium. In systems of electrical communication, the band of signal frequencies required is superimposed upon the carrier frequency in a process of modulation. Each set of side bands may be identified and separated from all others on a carrier-frequency-selection basis, usually by assigning a separate carrier-frequency band or channel for each different kind of service, station, or message.
3. The *transmission* of the electrical representation of the intelligence from the sending end and its reception at the receiving end of the system.
4. The *retranslation* of the received electrical representation of the information into a form of energy that is capable of affecting the senses of the recipient to produce a subjective sensation essentially the same as that of which the original intelligence formulation was capable, or of effecting some intended control operation.

10. Functional Elements. These considerations permit the establishment of fundamental sequential steps and concepts. Let i represent the intelligence, e the electrical form of the energy corresponding to this intelligence, t designate time, and let the subscript 1 designate those functions or operations occurring at the transmitting portion of the system and the subscript 2 operations occurring at the receiving end. With this notation, the functional operations in any electrical communication system may be expressed, symbolically, as

$$i_1(t) \rightarrow e_1(t) \rightarrow e_2(t) \rightarrow i_2(t)$$

in which the arrows indicate the direction in which the operations proceed. This form of representation expresses the four fundamental energy conversions enumerated above, for an ideal system free from noise, interference, or distortion.

11. Correlation of Transmitting and Receiving Functions. Aside from the speed of transmission, two characteristic features of the over-all system are primarily responsible for its effectiveness and versatility.

The first is the manner in which the signal or information to be conveyed is impressed upon the carrier and extracted from it. In some systems the modulating and demodulating methods are sufficiently simple and independent of each other that (except that both must be responsive to the same carrier-frequency channel) the transmitter and receiver may be designed separately and still be capable of operating together as a unified system. In more sophisticated techniques the modulation and demodulation functions must be correlated and interrelated to function as a unified whole. This is especially true when operations at the receiving end must be synchronized with those at the transmitting end. For such systems the transmitter and receiver cannot be designed as independent and unrelated units if success is to be achieved; from the beginning, both must be planned as integrated elements.

The second characteristic feature is the manner in which the wave emitter at the transmitting end and the wave interceptor at the receiving end may be operated conjointly to determine the transmission path between the two and to take advantage of its propagation properties. In some of the simpler radio systems in which transmitting and receiving apparatus may be designed separately, the wave emitter and the wave interceptor may be randomly related. In more complex and efficient systems there is a tendency to employ directional properties of transmitting and receiving antennas to propagate electromagnetic energy in a reasonably well defined transmission path. The emitter and interceptor may be oriented in azimuth and in elevation. In some kinds of service the directional properties of the radiating and receiving antennas may also be altered at different times, and in this case time synchronization of transmitting- and receiving-antenna structures is required. When this is the case, the transmitter and receiver can no longer be designed or operated without regard to performance at the other end of the system.

The interrelationships between transmitting and receiving operations with respect to modulation methods, synchronization of operations, and propagation path may be illustrated by considering the over-all performance and requirements of a number of different kinds of typical radio systems.

12. Radio Telegraphy. In these systems, the different letters that spell out words are resolved into elementary step functions, represented by dot-and-dash impulses, suitably spaced in time. Initially, therefore, telegraph signals are essentially created as a sequence of single-valued time functions. Each symbol for a letter, numeral, or mark differs from all others by a distinctive and unique combination of the active and inactive periods of each dot-dash-space combination of the code by which the letters are expressed. By keying, some property of the carrier wave is modified or modulated in accordance with the intelligence. The keying operation imparts information to the carrier and therefore it is, functionally, equivalent to an electrosensory transducer. After the modulated or keyed carrier wave passes through the system, the signal information is extracted in such a way as to actuate a loud-speaker, sounder, buzzer, recorder, meter, teletypewriter, or other electrosensory transducer to make the dot-dash symbols visible or audible. The receiving equipment must be tuned to the spectrum occupied by the carrier and its side bands, and it must have suitable demodulating apparatus, but otherwise the design of the receiver can be quite independent of the design of the transmitter, at least so far as concerns radio-telegraph systems employing manual keying.

13. Radiotelephony. In telephony, intelligence is conveyed by uttering, syllable by syllable, the words of sentences making up the intelligence. For speech, music, or other sounds, only one value of sound pressure is produced at any instant of time so that the original form of the signal is created as a single-valued time function. By a microphone and suitable modulating apparatus, some property of the carrier is modulated as a single-valued function of time in accordance with the instantaneous sound pressure of the original signal. After passage through the medium, the intelligence is

extracted from the received modulated wave by a demodulator, and the demodulated signal actuates a headset or loud-speaker to reconstruct the original signal. Again, the receiver must be tuned to the carrier channel and it must have suitable demodulating apparatus, but otherwise receiver and transmitter can be designed and operated independently.

14. Picture Transmission. Visual-image transmission, on the other hand, presents problems not encountered in sound transmission. A picture or visual image is seen, subjectively, by each eye as a two-dimensional area. To be suitable for transmission by electrical means, the images must be resolved into a single-valued function of time. Usually the problem is simplified somewhat by neglecting the fact that the two eyes see slightly different views as a result of their separation by the interpupillary distance, and by selecting for transmission a single view as might be seen by either eye alone.

As a first step, the scene is divided into an orderly array of comparatively minute areas or elements, each of which may be considered to be of uniform visual characteristics. The picture elements are then converted into single-valued time functions through a process of scanning and energy conversion carried out simultaneously. In the scanning process, the picture elements are progressively and systematically selected according to a prearranged sequence which automatically effects the necessary space-to-time conversion. As each picture element is successively selected, it is examined by an electrovisual transducer whose electrical output is related to some visual property of the picture element.

To accomplish the transmission of monochrome pictures by electrical means, some property of the signal wave may be varied in accordance with the visual luminosity of each picture element as it is scanned. The electrical transmission of colored images, on the other hand, requires that the complete picture or image be analyzed, on a color basis, into partial images. Each partial image contains or represents a different chromatic property of the complete scene, in such a way that the combination of all partial images, each properly chromatized, reconstructs the original color image. Each partial image must then be analyzed into picture elements which are systematically scanned, converted into electrical energy, and transmitted as single-valued functions of time.

For the transmission of still pictures, the time required for the scanning operation is not usually of critical importance, and it may extend over a number of minutes or even longer time intervals. For the transmission of visual images in which motion is to be portrayed, a number of additional complications are involved, including—primarily for psychological reasons—a maximum time during which the transmission of any given scene or image must be completed.

The visual effect of apparent motion is achieved through use of a series of instantaneous "still" views, known as *frames* or *fields*. Each frame or field thus represents the image at a given instant, and a series of such frames or fields is made with successive frames exposed in sequence for comparatively short intervals of time. When a series of such frames is properly recorded and subsequently viewed in the same order in which they were exposed, and when the successive frames follow one another with sufficient rapidity to minimize objectionable flicker, the subjective effect is that of apparent motion. The apparent speed of motion of moving objects when successive frames are viewed will be the same as the actual speed of motion of the object photographed when the speed at which successive frames is viewed is the same as the speed with which successive frames were exposed.

To produce the effect of apparent motion without objectionable flicker, the viewing rate is usually about 24 to 30 frames per sec or more. In the transmission of monochrome pictures, each frame or field is transmitted in about $\frac{1}{30}$ sec or less. If the pictures are in color, each frame or field must be resolved into its partial color images. There are usually three partial images per frame and since all partial images of the same frame or field are to be transmitted in about $\frac{1}{30}$ sec, each partial image should be transmitted in about $\frac{1}{100}$ sec. Although variations of this method are possible,

the outline given here is sufficient to indicate the general requirements for transmitting still or motion pictures, either in monochrome or in color, by electrical means.

At the receiving end of a picture-transmission system, the single-valued time function representing the scanned image must be reassembled or reconstructed into a spatial display or array of monochrome or color picture elements in such a way as to produce an image closely resembling the original. This operation requires that certain functions at the receiving end of the system be synchronized with the corresponding complementary functions performed at the transmitting end.

If the system is to operate satisfactorily as a unit: (1) the order in which elements are reconstructed for each frame at the receiving end must be identical to the order in which the image is analyzed at the transmitter; (2) the rate of re-creating elements into a picture at the receiver must equal the rate at which the image is analyzed into picture elements at the transmitter; (3) the order in which partial color images are reconstructed at the receiving end must be the same as that in which the image was analyzed into partial color images (primary colors, or chromaticity, hue, and saturation) at the transmitting end; and (4) the relative positions of the re-created picture elements in each frame of the received picture must be the same as the relative positions of the elements into which the image is analyzed at the transmitting end. Thus, all operations in the synthesis of an image at the receiver must be synchronized with complementary operations in the analysis of the image at the transmitter.

Transmission and reception of pictures require that the transmitting and receiving apparatus must be designed and operated as a consistent, interdependent, synchronized system as a whole.

15. Broadcasting. To reach as large a potential audience as possible, broadcast transmitters are usually located in or near large concentrations of population. The radio signals are allowed to radiate from the transmitting antenna more or less uniformly in all directions along the surface of the earth, although some directivity is often provided to minimize interference from other broadcasting stations, or to maximize the potential audience. Receiving systems for broadcast reception are not especially directive. So long as signals from the broadcast transmitter can be received more or less reliably, there is not much need to correlate or integrate the wave-emitting and wave-intercepting apparatus in broadcast systems.

16. Point-to-point Communication. For point-to-point communication, the objective is usually that of transmitting the largest possible signal most reliably from a given point to some other given point and so there is usually distinct advantage in not having the signal available for interception at intermediate points. A high degree of directivity in emitting or propagating the signal is usually desirable; a high degree of sensitivity of the receiving apparatus in the direction from which the signals arrive is also usually desirable.

The directivity or nondirectivity with which radio signals are propagated and intercepted depends primarily upon the design of the antennas at the transmitter and at the receiver. It also depends upon the propagation characteristics of the earth's surface atmosphere. The degree of directivity that can be achieved practically and economically is roughly proportional to the carrier frequency. Directional-transmission properties are closely associated with the propagation characteristics of the radio spectrum, as indicated by ultrahigh-frequency systems employing forward scatter, for example.

For the directive properties of a radio system to be utilized most effectively, it is necessary that directive antennas at both ends of the circuit be properly correlated in azimuth, and it may also be required that they be correlated in elevation angle, especially if directive communication is to be carried on over long distances.

17. Radio Direction-finding Systems. Direction-finding systems are designed so that the location of a radio transmitter can be determined from the radio signals of known modulation and radiation characteristics. One method (which does not require special equipment at the transmitter) requires that fixed receiving stations with variable directive antenna systems simultaneously take bearings on signals from

the transmitter whose location is to be ascertained. By methods of triangulation, directional bearings from two or more d-f stations are plotted on a map. The point where such triangulation "fixes" intersect determines the location of the station whose position is desired. In other systems, such as loran, for example, signals of known directivity or of known modulation or timing characteristics are transmitted from fixed stations whose positions are precisely known. By means of suitable receiving equipment, operators can determine their position without depending upon fixed stations to determine location "fixes" by triangulation or similar methods.

Radio beams of known azimuthal directivity and elevation are employed in a number of instrumental landing systems. Signals of suitable directivity pattern are radiated by fixed stations so that, by means of appropriate receiving apparatus and indicators, airplanes may land without visual reference to the ground. Directive beams for course determination may also be modulated to indicate "on-course" or "off-course" information or to convey other information besides that of directivity and distance from the transmitting station.

18. Radar Systems. Radio detection and ranging techniques make it possible to detect the presence and determine the character of material objects, and to determine their direction, distance, and elevation. Although radar signals may be generated as continuous waves, or may be frequency- or pulse-modulated, pulse modulation is now almost universally employed.

In pulse-modulated radar systems, pulses of r-f energy of about 1 to 50 μsec duration are radiated in a sharply directed beam. After the pulse has been emitted, the transmitter is shut off and a receiver, nearby, is turned on to receive the echo from a material object. When all echoes from one pulse have been received the transmitter is turned on again to send out another pulse, and the process is repeated at a rate of perhaps 1,000 times per sec. The echoes of pulses are picked up by a directive antenna and are displayed as a pattern on the screen of a cathode-ray tube. From the patterns produced by such echoes, the range and direction, or the distance and elevation of distant objects can be determined.

The directional antennas for transmission and reception in radar systems operate conjointly. This is automatically achieved if the same antenna is used for reception as for transmission. The pulse duration and repetition frequency of signals emitted by the transmitter must be synchronized and correlated with the scanning circuits of the cathode-ray-tube system in the receiver to produce a pattern that can be interpreted in terms of range and direction. Radar systems therefore represent a kind of radio-communication method in which both the wave directive properties and the demodulating and modulating operations of the transmitter and receiver must be simultaneously synchronized in a wholly coordinated system.

19. Radio System as a Whole. One purpose of this chapter is to outline, broadly, the general method of operation of various representative types of radio-communication systems. Another is to show how the complexity of the systems—and especially the interdependence of transmitter and receiver design—is related to the rate at which information is conveyed. The interdependence of receiver and transmitter design is especially important so far as concerns: (1) frequency of carrier wave; (2) the nature, timing, or synchronizing of the modulation and demodulation functions; and (3) the correlation or synchronization of the time and space directivity patterns of the emitting and intercepting apparatus.

20. Functional Elements. A block diagram representing the functional elements of a radio-communication system is shown in Fig. 1. For simplicity, the sources of power with which the equipment must be associated have been omitted. The information to be transmitted, and represented by $i_1(t)$, is converted into electrical form by a transducer. The output of the transducer, together with the output of a carrier generator, is fed to a modulator unit where the carrier wave is modulated by the signal wave in accordance with the information represented by $i_1(t)$. The modulated carrier wave $e_1(t)$ is radiated and propagated in the desired direction by an emitter, which may be a wave guide, transmission line, or antenna.

At the receiving end of the system, the intercepted energy is converted into voltage variations $e_2(t)$ by a wave interceptor or antenna. By amplifying, conversion, and demodulating apparatus, $e_2(t)$ is (usually) magnified and is converted into sense-perceptory energy by the transducer whose output is $i_2(t)$.

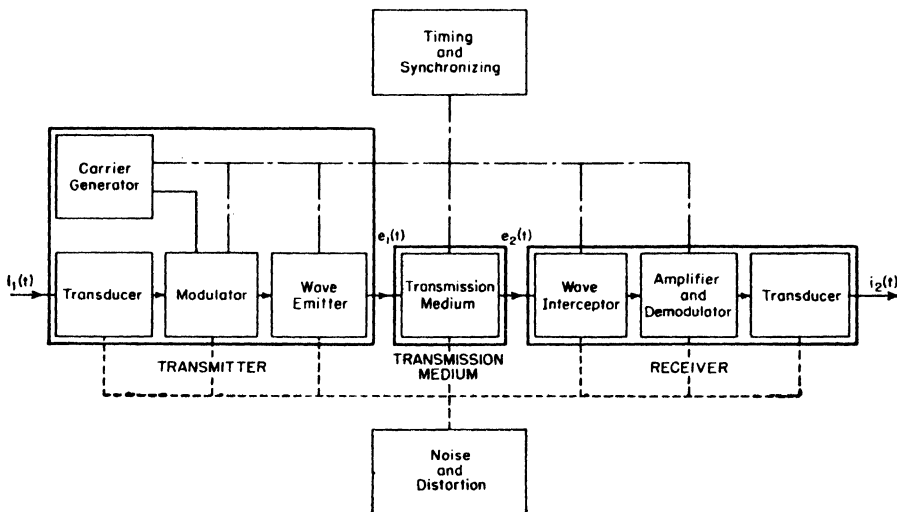
The demodulating and wave-intercepting operations at the receiver may require timing or synchronizing operations related to the modulating and wave-emitting operations at the transmitting end. Such timing and synchronizing operations may employ frequency-control apparatus at each end of the system, or the timing and synchronizing operations at the receiving end may be controlled by suitable timing pulses or signals generated in the transmitter, present in the transmitted wave, and


FIG. 1. Functional elements of complete radio-communication system. Signal or intelligence $i_1(t)$ is fed into the transmitter and emerges as electrical function of time $e_1(t)$, passes through transmission medium whose output is $e_2(t)$, and through receiver whose output is $i_2(t)$. Noise and distortion may be introduced at several points, as indicated by dashed lines. In certain systems timing or synchronizing operations between the transmitter, transmission system, and receiver may be required (as in television or radar systems, for example) in order for the system to function properly.

actuating or initiating the operations of frequency or time-control circuits at the receiving end. Such timing and synchronizing functions are indicated in Fig. 1 as being common to both ends of the system. Because such interlocking frequency-control, timing, or synchronizing methods are not required in all radio systems, they are indicated by dashed lines rather than by solid lines.

Noise and distortion may be introduced into the system at a number of different points, although usually most noise is introduced in the transmission system as shown by the dashed lines. Once introduced, however, the deleterious effects of noise and distortion are encountered at all points to the right of their introduction in Fig. 1.

21. Signal Frequencies vs. Amount of Information Transmitted. To be useful in representing intelligence, each symbol expressing a certain amount and kind of intelligence must be different from every other symbol expressing a different amount and kind of intelligence. In other words, each symbol, along with the meaning it expresses, must be unique. Using such symbolic notation, the communications engineer is interested in determining the mechanism by which a quantitative measure of nformation can be developed.

The amount and precision of information or intelligence conveyed depend upon the

number and sequence of the symbols selected. Hence the number of symbols required to convey the desired amount of information may be taken as a quantitative measure of information. The significance or meaning of the intelligence transmitted depends not alone on the number of symbols selected, but also upon their arrangement or the order or sequence of selection. This point of view has the great practical advantage of being objective and completely divorced from physiological factors.

If information is measured quantitatively by the number of selections required, the rate at which information is conveyed depends upon the number of symbols selected per unit of time, or upon the rate of speed of symbol selection. It follows that the rate of conveying intelligence depends upon the frequency with which elementary choices are made to select the symbols. The common and frequently used symbols may be represented or expressed by simple or easy choices or selections, whereas the unusual or infrequently used symbols may be represented or expressed by a more complex selection process requiring more choices for final selection.

A band of frequencies is required to transmit information, and the band needed in any particular case depends upon the rate at which information is transmitted. Typical values of signal band widths normally required for several different kinds of communication systems are given in Table 1.

The relationship between band width and information was first clearly stated by Hartley, who enunciated the following important principle of communication:[1]

The maximum rate at which information may be transmitted over a system whose transmission is limited to frequencies lying in a restricted range is proportional to the frequency range. From this it follows that the total amount of information which may be transmitted over such a system is proportional to the product of the frequency range which it transmits by the time during which it is available for transmission.

Table 1. Signal-frequency Band Widths Required for Various Kinds of Radio-communication Service

Kind of Service	Typical Band Widths, Cps
Manually keyed telegraphy (25 words/min)	0–100
Tone-modulated telegraphy (speed of 25 words/min, 1,000 cps tone)	0–2,100
Commercial telephony, single side band	0–3,000
Commercial telephony, double side band	0–6,000
High-quality single-side-band telephony	0–5,000
High-quality double-side-band telephony	0–10,000
Exceptionally high quality single-side-band telephony	0–20,000
Exceptionally high quality double-side-band telephony	0–40,000
Facsimile, 8- × 10-in. picture, 100 lines/in. transmitted in 10 min with 1,000-cps tone	0–4,000
Low-definition television (180 lines, 24 frames/sec)	24–410,000
Good-definition television (525 lines, 30 frames/sec)	30–4,350,000
High-definition television (1,029 lines, 30 frames/sec)	30–16,650,000
Frequency-shift telegraphy	0–1,800
Commercial frequency-modulated telephony	0–36,000
High-quality frequency-modulated telephone broadcasting	0–200,000
Frequency-modulated facsimile (8- × 10-in. picture, 100 lines/in., transmitted in 10 min with tone of 1,000 cps)	0–14,000

22. Modulation. The information to be transmitted is contained in, or represented by, the frequency spectrum of the signal or message. The message is adapted to transmission by converting signal variations into single-valued time functions of electrical energy through the use of suitable transducers. For all practical purposes in well-designed systems, the frequency spectrum of its electrical representation is the same as that of the original form of the message. Electrical energy at signal frequencies is not usually in a form useful for direct transmission through the medium of propagation, but it can be converted into proper form by a process of modulation in which the properties of the carrier wave and the signal wave are combined.

A carrier wave has such properties as will enable it to be propagated through the transmission medium. A signal wave is a wave conveying some intelligence, message, or effect. Modulation is the process of modifying some characteristic of a carrier wave

[1] Hartley, R. V. L., Transmission of Information, *Bell System Tech. J.*, **7** (3), 535, July, 1928.

in accordance with the signal wave, the result of such modification being a modulated wave, which is therefore a combination of the carrier and signal waves.

Information may be transmitted continuously, or it may be transmitted intermittently. The first method is represented by voice signals or music, the second by radar pulses or by the characters of a telegraph code. These two ways of transmitting information give rise to two fundamentally different methods of modulation—continuous, and intermittent or pulse.

In continuous methods of modulation, some property of the sinusoidal carrier frequency is continuously altered by the information to be transmitted. If the amplitude of the carrier is modified, amplitude modulation results. The argument of the sinusoidal carrier may also be modified by the signal. In this case angle rather than amplitude modulation results. Angle modulation may be subdivided into two related types. If the frequency of the carrier is varied by the signal, frequency modulation results, whereas phase modulation results if the phase of the carrier is altered.

In pulse modulation, the information is not projected continuously, but rather as discrete signal elements, usually short pulses. The message is sampled by the pulses, and some property of the pulses is then modified by the character of the signal to be transmitted. Pulse-modulation methods may be divided into unquantized or ordinary pulse modulation, and quantized or pulse-code modulation methods. By *quantization*, we mean that a large range of quantities may be divided into a set of small ranges, each of which is assigned a single discrete quantity. Quantization permits the approximate representation of a continuously varying function by a set of discrete values. The difference between two adjacent discrete values is called a quantum.

If the amplitude of the pulses is continuously variable in accordance with the signal to be transmitted and the timing of the pulses is unchanged or independent of the signal, ordinary or unquantized pulse-amplitude modulation results. If the time properties of the pulses are continuously altered, pulse-time modulation results. Thus, by modifying the duration, position, or frequency of the pulses continuously in accordance with the signal, ordinary or unquantized pulse-time modulation may be designated, respectively, as pulse-duration modulation, pulse-position modulation, or pulse-frequency modulation.

In pulse-code modulation the signal wave is sampled at discontinuous intervals determined by pulses, and is then quantized and coded. Quantization is accomplished by rounding off the value of the signal to the nearest one of a finite set of permitted values at each sampling step. Such quantization permits the signal to be transmitted by codes, such as the familiar telegraph code.

No matter whether continuous or pulse-modulation methods are involved, the modulated wave contains new frequencies not present in either the carrier or the signal wave. These new frequencies are composed of the sums and differences of the carrier and signal frequencies, and are called side-band frequencies. The signal frequencies are usually low compared with the carrier frequency so that, in most practical cases, either or both side bands are of substantially the same frequency as that of the carrier; it is the high-frequency characteristic of the modulated wave imparted to it by the carrier that permits it to pass through the propagation medium.

All essential signal information is contained in either one of the side bands. It is unnecessary, therefore, to transmit both side bands, or, for that matter, even the carrier frequency. In most radio systems, the carrier frequency is transmitted; otherwise it must be provided locally in the receiver. Total or partial elimination of one of the side bands reduces the frequency spectrum or channel band width required for transmitting a given kind of signal.

Since modulation is a complicated process, the question naturally arises as to why modulation is necessary. Most importantly, it imparts intelligence to the carrier. In radio communication, and also in many kinds of telegraphy and telephony, modulation is necessary as a means for conveying signals from one point to another. Modulation is also employed to achieve desirable characteristics in communication. For

example, the signal-to-noise ratio may be improved through suitable methods of modulation, the effects of natural or man-made static may be drastically reduced, or the frequency spectrum available for communication services may be more effectively utilized.

23. Frequency and Phase in Modulated Waves. A sinusoidal variation with constant amplitude and uniform phase shift per unit time is characterized by a fixed and constant single frequency. Such a constant frequency is a feature of an unmodulated carrier wave and is commonly encountered in communication systems. When the carrier is modulated, however, the resultant wave is no longer characterized by a single constant frequency or phase shift, and it is necessary to devise new concepts and definitions for the instantaneous values of frequency and phase of waves more complicated than simple harmonic variations.

Frequency is the time rate of change. Hence the angular frequency ω is the time rate of change of the phase angle θ; conversely phase angle θ is the integral, with respect to time, of the frequency ω. With these concepts and definitions, we are no longer required to deal with constant values of frequency and phase shift; instead we can define instantaneous values of these terms.

The instantaneous angular frequency, in radians per second, is

$$\omega_i = \frac{d}{dt}\,\theta(t)$$

when the phase shift is a function of time $\theta(t)$ and is equal to $2\pi f$, where f is the frequency in cps.

When the phase shift and frequency vary with time, the instantaneous value of the phase shift is

$$\theta(t) = \int \omega_i \, dt$$

where ω_i is the instantaneous angular frequency in radians per second.

The expressions for instantaneous frequency and instantaneous phase shift are applicable, of course, to the case when these factors are constant with respect to time. But the particular value of these terms lies in their application to time-varying phenomena, such as are encountered in processes of modulation.

24. Amplitude Modulation. In amplitude modulation the amplitude of the carrier wave is varied in accordance with the signal. The resultant modulated wave is no longer of constant single frequency but contains frequencies that are the sums and differences of the carrier and signal frequencies. The new frequencies are called side frequencies; if the signal is composed of a single sinusoidal wave, the spectrum of the modulated wave will contain the carrier frequency together with two side frequencies, one above and one below the carrier frequency and displaced from it, as mirror images, by an amount equal to the signal frequency. If the signal is composed of a line or continuous band spectrum, the side bands will also be line or continuous band spectra as mirror images on both sides of the carrier frequency. The side bands contain the information imparted to the carrier wave by the signal in the process of modulation. If allowance is made for the fact that the modulation process shifts the frequency of the signal by an amount equal to the carrier frequency, the spectrum of each of the side bands is usually the same as that of the original modulating wave or signal.

Consider a sinusoidal carrier wave of instantaneous value

$$i = I_c \cos(\omega_c t + \phi_c)$$

where I_c = amplitude of the carrier wave

$\omega_c = 2\pi f$ = angular frequency of carrier wave, radians per sec, and f = cyclic frequency, cps

ϕ_c = relative phase of carrier wave at time $t = 0$

Let the carrier be amplitude-modulated by $f(t)$, a sinusoidal time variation with angular frequency ω_s, of relative phase ϕ_s. Let

$$f(t) = [1 + m \cos(\omega_s t + \phi_s)]$$

where m is the modulation factor and lies between 0 and 1. Such a signal wave always has positive value and when applied to vary the amplitude of the carrier wave produces a modulated wave expressed by

$$\begin{aligned} i &= I_c[f(t)] \cos(\omega_c t + \phi_c) \\ &= I_c \cos(\omega_c t + \phi_c) && \text{carrier} \\ &\quad + \tfrac{1}{2} m I_c \cos[(\omega_c + \omega_s)t + (\phi_c + \phi_s)] && \text{upper side band} \\ &\quad + \tfrac{1}{2} m I_c \cos[(\omega_c - \omega_s)t + (\phi_c - \phi_s)] && \text{lower side band} \end{aligned}$$

In the process of modulation, the constant amplitude of the carrier has been modified by the signal wave $f(t)$, which now serves to define or outline the envelope of the modulated carrier wave. Since the amplitude is no longer constant, the single-frequency carrier has been expanded into a line spectrum, and, in general, at any instant, the modulated wave has an "instantaneous frequency" different from that of the carrier frequency.

The communication band width is the frequency spectrum occupied by the carrier and all upper and lower side-band frequencies. The carrier frequency is a single frequency conveying no information, but the above equations show that either the upper or the lower side band alone contains all the information of the original signal, by including the terms in ω_s. The frequency of the side bands has been shifted, however, with respect to the signal frequency, by an amount equal to the carrier frequency.

In general, the relative phase ϕ_s of each component of signal frequency in the modulated wave must be the same as that in the original form of the signal. This requirement may be relatively unimportant in some forms of communication, as in speech and music, since the ear is not sensitive to changes in phase shift; on the other hand, it is sometimes very critical, as in transmission of video signals for television.

If the modulation index m is zero, no signal information is conveyed to the carrier, whereas if $m = 1$, the envelope of the carrier wave (for sinusoidal signal wave) varies from zero to twice the value of its unmodulated amplitude. The average power in the carrier (which is proportional to I^2) remains constant. The power in each of the side bands cannot exceed 25 per cent of the average power in the carrier, and this occurs when $m = 1$. The total power in both side bands, therefore, cannot exceed half of that of the carrier for normal transmission of the modulated carrier. If the amplitude of the signal is increased relative to that of the carrier so that m exceeds unity, the carrier is said to be overmodulated; distortion results, and the useful power output in the side bands decreases.

Although the oldest and simplest form of modulation, amplitude modulation is not particularly effective or efficient compared with other methods of modulation.

25. Angle Modulation. In angle modulation the angle of a sinusoidal carrier is the parameter subject to variation by the modulating wave. Two forms of angle modulation are of practical value, (1) frequency modulation and (2) phase modulation. These forms of modulation are related, and sometimes both exist simultaneously in the same system.

In *frequency modulation* the instantaneous frequency of a sinusoidal carrier is made to depart from the constant unmodulated carrier frequency by an amount that is proportional to the instantaneous value of the signal or modulating wave.

To derive an expression for the current of a f-m wave, let the carrier current be

$$i = I_c \cos(\omega_c t + \phi_c)$$

and let the signal or modulating wave be $-\Delta\omega_c \sin \omega_s t$. Then, the instantaneous frequency of the modulated wave is

$$\omega_i = (\omega_c - \Delta\omega_c \sin \omega_s t) = \frac{d}{dt}\,\theta(t)$$

Now, $\theta(t) = \int \omega_i\,dt = \omega_c t + (\Delta\omega_c/\omega_s) \cos \omega_s t$, so that the modulated wave takes the form

$$i = I_c \cos\left(\omega_c t + \frac{\Delta\omega_c}{\omega_s} \cos \omega_s t\right)$$

For sinusoidal modulating waves, the frequency deviation of a f-m wave is $\Delta\omega_c/\omega_s$ radians per sec.

If the above expression is expanded and the terms grouped according to frequency components,

$$i = I_c \sum_{n=-\infty}^{\infty} J_n\left(\frac{\Delta\omega_c}{\omega_s}\right) \cos\left[(\omega_c + n\omega_s)t + \frac{n\pi}{2}\right]$$

where $J_n(\Delta\omega_c/\omega_s)$ is a Bessel function of the first kind and nth order with argument $\Delta\omega_c/\omega_s$.

The degree of modulation is usually defined as the ratio of the actual frequency deviation $\Delta\omega_c$ to the maximum frequency deviation $\Delta\omega_{c_{max}}$ of which the system is capable, or which is permitted by law.

In *phase modulation* the linearly increasing phase of the unmodulated carrier has added to it a time-varying phase angle whose magnitude is proportional to the amplitude of the applied modulating wave or signal.

To write an expression for the phase-modulated wave, the time-varying component of the phase angle must be proportional to the amplitude of the applied signal wave. Let the signal wave be $\Delta\phi \cos \omega_s t$ and let the unmodulated carrier be $i = I_c \cos (\omega_c t + \phi_c)$ as before. Then the modulated wave becomes

$$i = I_c \cos [\omega_c t + (\phi_c + \Delta\phi \cos \omega_s t)] = I_c \cos \phi(t)$$

where $\Delta\phi$ is the phase deviation factor of the resulting wave, expressed in radians. The instantaneous radian frequency ω_i is the time rate of change of phase angle $\theta(t)$ or

$$\omega_i = \omega_c - \omega_s \, \Delta\phi \sin \omega_s t$$

For sinusoidal modulating wave, the frequency deviation of the phase-modulated wave is $\omega_s \, \Delta\phi$ radians per sec.

If the above expression for the modulated wave is expanded, and terms are grouped according to frequency components, the phase-modulated wave is expressible as

$$i = I_c \sum_{n=-\infty}^{\infty} J_n(\Delta\phi) \cos\left[(\omega_c + n\omega_s)t + \frac{n\pi}{2}\right]$$

where $J_n(\Delta\phi)$ is a Bessel function of the first kind and nth order with argument $\Delta\phi$.

In *phase modulation*, the phase $\theta(t) = \phi_c + \Delta\phi \cos \omega_s t$ is varied in accordance with the signal. The quantity $\Delta\phi \cos \omega_s t$ is called the phase deviation and is expressed in radians. The degree of modulation is usually defined as the ratio of the actual phase deviation $\Delta\phi$ to the maximum phase deviation $\Delta\phi_{max}$ of which the apparatus is capable at any moment, or is permitted by law. Thus, for phase modulation the degree of modulation is defined in terms of the properties of the system in which it is used, and not alone in terms of properties of the signal and carrier, as in the case of amplitude modulation.

26. Some Properties of Angle-modulation Systems. In f-m systems the deviation of the instantaneous frequency from its unmodulated value is proportional to the magnitude of the modulating wave and is independent of the frequency of the modulating signal. On the other hand, in phase-modulation systems the deviation of the instantaneous frequency from its unmodulated value is proportional to the derivative of the modulating wave. Thus, although phase modulation and frequency modulation are particular forms of angle modulation, they are not essentially different, and one can be converted into the other.

There is, in fact, no important difference between a frequency- and a phase-modulated wave so long as modulation is accomplished by a single sinusoidal frequency, except a difference in degree of modulation. If the modulating signal has components of many

frequencies, however, then there is definitely a difference; f-m phase-modulated signals have greater deviation at the higher modulating or signal frequencies.

Angle-modulation systems have important noise-reduction properties, particularly for random noise, provided the signal level exceeds the noise level. When the signal-to-noise ratio is greater than unity, and preferably is greater than unity with a safe margin, the noise-reduction properties of angle-modulation methods are primarily due to two factors. The modulating signal produces a much larger deviation of the carrier frequency than is produced by a random distribution of side bands. In addition, superposition of random noise on a wide-band angle-modulated carrier produces modulation frequency components too high to pass through an audio system, so that these components are not heard as noise. Only the side bands produced by noise whose frequency components are close to that of the unmodulated carrier produce noise in f-m systems, and these are relatively ineffective in producing f.m. The signal has effective side bands far removed from the carrier, and all of these act together to produce the swing or deviation at the signal frequency.

27. Carrier and Side-band Suppression. When a carrier of constant angular frequency ω is modulated by a signal, the frequency of the modulated carrier is broadened. The modulated carrier contains frequencies of the carrier frequency, and bands of frequencies above and below the carrier frequency and displaced from it by the frequency of the signal component. These frequencies above and below the carrier frequency are called the upper and lower side-band frequencies, respectively. The frequency spectrum occupied by the carrier and both side bands is called the communication band width.

In amplitude modulation, the communication band width is twice the frequency of the highest-frequency component of the original signal which is transmitted. Thus a broadcast channel having a band width of 10 kc and transmitting both side bands is capable of transmitting signal components in each side band up to 5 kc; to provide some spectrum separation between adjacent channels, signals of somewhat less than 5 kc could be accommodated in channels 10 kc wide.

In angle modulation, there exists an infinite number of pairs of harmonic side frequencies, spaced above and below the carrier by positive multiples of a single signal frequency. Not all these frequencies are important, however, and the maximum value of n which need be considered for a given modulation index m is expressed empirically by the relation

$$n_m = m + km^{0.27}$$

where $k = 2.4$ for $J_n(m) = 0.01$, and $k = 3.5$ for $J_n(m) = 0.001$.

Since all the information of the signal is contained in either of the side bands, it is unnecessary to transmit both side bands. One side band may be removed, and the portion of the frequency spectrum from which the side band is removed will then be available for other services. One of the side bands may be removed by means of filters having very sharp cutoff properties, so that the carrier and one side band are transmitted while the other side band is eliminated. Single-side-band transmission may also be accomplished by removing one of the side bands by means of a phase-balancing process instead of filtering. In the phasing method, two carriers are generated with 90-deg phase shift between them, and these are modulated by two signals which also have a 90-deg phase shift between them. The output of the two modulators consists of the carrier and one side band, the other side band being removed by cancellation of phases in the two modulating units.

Sometimes it is not desirable or feasible to remove all of one side band, but merely most of it, particularly at the higher signal-frequency components. *Vestigial side-band transmission* then results.

Carrier suppression is the process of removing the carrier component in a modulated signal, leaving one or both of the side bands. Removal of the carrier results in no loss of signal for the carrier contains no information. An appreciable saving of transmitted power may be achieved by not transmitting the carrier, with resultant increase

in the transmitter efficiency, for in the absence of a modulating signal no power is transmitted. Even when signals are transmitted, a larger fraction of the transmitter power may be applied to the side bands instead of delivering it to a carrier conveying no information. For carrier-suppression systems, a carrier of proper frequency and phase must be supplied at the receiver. Since it is not always easy to achieve local generation of a carrier of proper frequency and phase, some systems transmit a portion of the carrier. The low-amplitude carrier transmitted in this case may then be used to control the locally generated carrier in the receiver.

28. Need for High-frequency Carriers. For intelligence-bearing signals to be propagated by electromagnetic waves, it is necessary that the electric and magnetic components of the wave interact with each other to support and sustain the process of propagation. This condition requires the generation of displacement currents of appreciable magnitude, and these are produced when the carrier frequency is comparatively high. Practical radio communication depends upon the employment of carrier frequencies greater than (and usually very much greater than) about 10 kc; carrier frequencies may extend to several thousand megacycles, *i.e.*, to the region of 10^9 cps or more.

The band width of the modulated carrier should be a small fraction of the unmodulated mean carrier frequency. This limitation requires that the carrier frequencies be very much greater than the highest signal frequency to be transmitted. This restriction also requires very high carrier frequencies for those kinds of communication in which a considerable amount of information must be transmitted in a short interval of time (as in television or radar systems) or where the properties of the system necessitate reasonably large excursions from the mean carrier frequency (as in f-m systems).

Table 2. Relations between Carrier Frequency and Band Widths for Various Classes of Radio Communication

Type of service	Typical carrier frequency, Mc	Typical band width, cps	Ratio of max band width to carrier frequency
Long-wave telegraphy	0.100	0–100	0.001
Aeronautical telephony	0.200	100–3,000	0.015
Mobile (emergency) telephony	0.50	100–3 000	0.006
Broadcast telephony	0.600	40–5,000	0.0083
Broadcast telephony	1.00	40–5,000	0.005
Broadcast telephony	1.50	40–5,000	0.003
Loran	1.90		
Standard frequency (tone modulation)	2.50	600	0.00024
Amateur telephony	7.25	100–3,000	0.00041
Emergency frequency	8.28		
Short-wave broadcasting	11.50	40–5,000	0.0004
Television channel 2	54–60	30–4,500,000	0.082
Marker beacon	75		
Television channel 6	82–88	30–4,500,000	0.055
F-m broadcasting	88	20–20,000	0.00024
F-m broadcasting	108	20–20,000	0.00018
Emergency frequency	140	100–3,000	0.00002
Television channel 7	180–186	30–4,500,000	0.025
Television channel 13	210–216	30–4,500,000	0.021
Long-wave radar (300 cm)	100	0–200,000	0.002
Microwave radar (10 cm)	3,000	0–500,000	0.0001
Microwave radar (3 cm)	10,000	0–500,000	0.00005

The ratios of the maximum signal frequency to the (mean) carrier frequency for typical classes of radio service are given in Table 2. These data show that the band width for the modulated carrier frequency is, at most, but a few per cent of the mean carrier frequency for practical systems.

29. Method of Solving Electrical-communication Problems. Solving many problems in electrical communication involves the following steps:

1. The differential equations expressing the dynamic equilibrium of the system are set up with initial and boundary conditions specified.
2. The functions satisfying those sets of equations are determined by a process of integration which yields the formal solution to the problem. The formal solution thus found is more general than is required for a particular solution.
3. The formal solution must then be subjected to the initial conditions of the system, as well as to the boundary conditions of time and space to obtain the solution for the particular problem under consideration.

The need for analytical treatments of communication problems thus becomes clear. To be useful for communication purposes, however, the differential equations of dynamic equilibrium of the communication system, as well as their formal solutions, must be expressible in terms of information-bearing signals. It becomes necessary, therefore, to obtain quantitative expressions for the representation of intelligence in developing an analytical approach to communication engineering. Such expressions should be as simple as possible, for mathematical manipulation, consistent with the requirement that they be sufficiently rigorous and useful for engineering and scientific work.

ANALYTICAL APPROACH TO COMMUNICATION ENGINEERING

30. Theories of Communication. The general problem of electrical communication is to: (1) accept, at the transmitting end of the system, the message to be conveyed, (2) transform the message into such form as will permit its passage through the communication system, (3) convey or transmit the electrical form of the message from a transmitting point to one or more receiving points, and (4) re-create a satisfactory replica of the original message at the receiving end of the system.

The term "message" is to be interpreted in a broad sense; it may mean any information-bearing function, *i.e.*, any concept or entity translatable into physical form capable of being measured or specified as a single-valued time function. The character of the message determines important features of the system (such as band width and power requirements) especially when considered in relation to interference such as distortion, noise, cross talk, and the like. As used in the above sense, the term "message" is synonymous with the term "information."

Views as to what constitutes information, and the means by which information can be expressed analytically, have had important bearings on the theories underlying communication engineering and the development of communication systems. Two theories have been effective in building up our present understanding of systems of communication, control, and information processing. These are the classical theory, which dominated thinking until the Second World War, and the statistical theory developed since about 1942.

31. Classical Theory. The classical theory of communication depends primarily upon application of the Fourier series and Fourier integral methods of expressing the single-valued time functions of the information to be transmitted. The Fourier series makes use of a number (which may be infinite) of harmonic functions of time to represent single-valued magnitude-time functions under steady-state conditions. The use of Fourier series implies that the harmonic functions representing the wave form have existed for an infinite length of time, and assumes that they will continue, unchanged, for an infinite period. The Fourier integral represents a single-valued aperiodic or transient magnitude-time function whose components, again, are assumed to exist unchanged for all time.

The wave form specified by a Fourier series may be expressed as a magnitude-time function in the time domain, or as a pair of line spectra in the frequency domain; in the latter case the amplitude and phase of each discrete harmonic component are

plotted as line functions of the frequency. A wave form expressed by a Fourier integral may likewise be represented in the time domain as a magnitude-time function; in the frequency domain it is represented by a pair of continuous amplitude and phase functions of frequency. A given function expressed in the time domain can be transformed into the frequency domain and vice versa by means of Fourier transformations. Fourier transforms have played an important role in classical communication theory. The classical point of view has been useful in determining important properties of the communication system, so long as the signals to be transmitted can be represented by periodic or aperiodic time functions.

According to the classical point of view, the recurrent or transient functions expressible by the Fourier series or integrals are the commodity which the communication system handles; such functions represent the information to be conveyed. If the information is to be expressed in terms of recurrent or transient wave forms, the Fourier theory determines the values of the information function for all values of time—past, present, and future. If a message is represented by a function of the type whose values are specified once and for all, for all values of the independent variable (usually time) the information expressed in this way must be such that its entire nature is precisely known and predictable. This point of view is in direct conflict with the very nature of information, for, to be useful, the flow of information must contribute some knowledge not previously known, and consequently must be unpredictable.

32. Statistical Theory. The proper functioning of the communication system requires that the fluctuating phenomena, containing the information for transmission from one portion of the system to another, must ultimately be re-created at the receiving end. The fluctuations of information may be represented by an array of unpredictable but measurable quantities distributed in time. It is the unpredictable nature of the message which makes it carry information. The fluctuating phenomena representing the information are best described in terms of statistics and probability; these branches of mathematics form the backbone of modern information theory, rather than the harmonic or singularity functions on which classical communication theory was built. According to modern theory, messages and noise are random processes and are, accordingly, dealt with analytically as such.

Whatever their source, messages to be transmitted are regarded as random time-varying functions or time series. The statistical character of the message is assumed to remain constant with respect to time, and hence may be represented by time series. Time series are discrete or continuous sequences of quantitative data assigned to specific moments of time. They are studied and evaluated with respect to the statistics of their distribution in time. In the case of simple time series, a single numerical observation exists at each moment of the discrete or continuous sequence. Multiple time series consist of a number of separate quantities evaluated according to a time common to all.

The random functions used to represent information in modern communication theory can never specify definitely the value of phenomena at a specified instant of time in the future. Because they do have known or assumed statistical properties, however, certain matters regarding the *probability* of the existence of the phenomena can be ascertained. For example, it is possible to determine the probability that one letter in the English language will be followed by some other letter, or the probability that a picture element of given reflection density in a scanning process will be followed by another element of half that reflection density. That is, the structure of the information is not only determinable on a statistical basis, but it is also precisely determinable. In studying the statistical structure of messages by random time series, a number of statistical parameters will be useful. The correlation function, amplitude distributions, and certain conditional probability distributions are among the most important of these.

The mathematics of modern information theory, as well as the mathematics of classical communication theory, represents general relationships between significant entities in the communication process. As such, mathematics of communication

theory represents a method or technique of thinking rather than a set of formulas which may be used, in an automatic crank-turning process, to extract numerical results for specific design purposes. In this respect, at least, the mathematics of information theory is analogous to Maxwell's equations, for example, which, although they provide the underlying foundations from which circuit-design formulas can be derived, are not immediately amenable and directly applicable to the solution of circuit behavior.

33. Differences between Classical and Statistical Communication Theories. The fundamental difference between these theories of communication lies in the recently developed concept of the nature of information. The unpredictable property of information, and the use of the mathematics of statistics and probability theory to represent random processes, require knowledge of topics (such as generalized harmonic analysis and theory of statistical operations) which have been but recently introduced into the field of practical communication engineering.

The new point of view regarding communication theory complements and expands the older classical point of view; it does not entirely replace or invalidate it. In evaluating the performance of a communication system, there is still need to consider periodic and aperiodic functions. But the introduction of the statistical theory opens up new avenues which, at present, appear to give much promise for new technical achievements. The new approach seems to be most promising in pointing the way for conserving band width, or of trading band width for power (or vice versa), in the design of prediction circuits and filters for separating noise from the desired signal, and in comparing or evaluating a given system with its theoretical limit of performance.

34. Time Functions Encountered in Communication Engineering. In a communication system the measurable varying quantities that are distributed in time to represent information are operated upon or processed in their passage through the system in a variety of ways. The time functions or time series representing information are usually continuous—or may be treated as being continuous, without appreciable error—and may be classified as periodic functions, aperiodic functions, and random functions.

A *periodic function* is one whose amplitude repeats a set of values (usually, but not necessarily, continuous) after the passage of a given interval of time. Any single-valued recurrent wave form represents a periodic function. Periodic functions are important in communication systems; for example, the carrier waves used in radio and wire telegraphy and telephony are periodic functions. Any single-valued periodic wave can be completely specified by the wave form for a single cycle, or by its amplitude and phase spectra. Since recurrent cycles of periodic phenomena are alike, the specifications for one complete wave or cycle are the same as those for any other complete cycle. Because all successive cycles of periodic phenomena are alike and can be completely specified by the amplitudes and phases of the harmonic components as functions of frequency, or by constructing the wave form (both of which are derivable from a single cycle of recurrent phenomena), no new information is conveyed if more than one cycle of phenomena is received. Hence, periodic phenomena are incapable of representing a continuous flow of information; in fact the information they can convey is exceedingly limited.

An *aperiodic function* is one which is devoid of periodicity, or for which the period is recurrent only if infinitely long. Aperiodic functions of time are singularity functions and are usually associated with transient phenomena. For purposes of analysis, aperiodic functions are usually expressed in terms of the Fourier integral which specifies the value of the function for all values of time. Aperiodic functions may be expressed by the wave form of the function, or by the amplitude and phase spectra which are now continuous spectra, rather than line spectra as is the case for periodic phenomena. Again, it is possible to specify the wave form of an aperiodic phenomenon for all values of time, and for this reason aperiodic phenomena, like periodic phenomena, are incapable of representing a continuous flow of information.

Finally, *random functions* are encountered in communication systems. By a random function is meant a single-valued function in which the instantaneous values of

the fluctuating phenomena are not subject to precise prediction, but whose statistical properties can be precisely evaluated. It is impossible to specify accurately the magnitude of a random function at any instant of time; all we can do is determine the statistical probability that the function will have a designated value—or will lie within a specified range of values—at any given instant. The fact that the value of random functions cannot be accurately predicted for any specified instant is precisely that characteristic property which makes them so useful in representing the flow of information. For purposes of analysis, random functions are evaluated by applying principles of generalized harmonic analysis to the random or statistically determined functions.

The three types of functions encountered in communication systems—periodic, aperiodic, and random—may each be represented by means of generalized harmonic analysis. Harmonic analysis applied to periodic functions gives rise to the simplest mathematical forms, whereas harmonic analysis applied to random or statistically determined functions is usually the least familiar to, if not the most difficult for, most practicing communications engineers.

35. Periodic Functions. The simplest type of periodic function is that which varies harmonically with respect to time. Such a function may be expressed in terms of three constants by an equation of the form

$$y = f(t) = E \sin (\omega t + \theta) = E \cos (\omega t + \phi)$$

where E is the amplitude or maximum value of the function, $\omega = 2\pi f$ is the angular frequency in radians per second if f is the cyclic frequency in cps, and θ and ϕ are phase angles relating the zero value of the sine or cosine function, respectively, with that instant of time from which it is assumed that the function has its initial, zero, or starting value.

Harmonic functions are mathematically simple to manipulate and represent quite accurately wave forms frequently encountered in electrical-communication systems. Moreover, sinusoids provide the basis for dealing with much more complicated wave forms, expressible by means of the Fourier series, since any periodic wave form may be represented by, analyzed into, or synthesized from, a series of harmonic functions with properly selected values of the three constants for each component term.

FIG. 2. Harmonic function plotted explicitly against time.

Harmonic functions involve three constants: the amplitude E, the angular frequency ω (or the cyclic frequency f), and the phase displacement, given above by θ or ϕ. When these three constants are known the harmonic function (either the sine or the cosine) is completely specified. In the time domain, harmonic functions may be illustrated graphically by the familiar sine-wave curve of Fig. 2. Such a representation has the value of illustrating, pictorially, the manner in which the function varies with time. From such an amplitude-time curve, the three constants (amplitude, frequency, and phase) may be determined.

An amplitude-time curve, such as that shown in Fig. 2, is a satisfactory method of representing the manner in which the magnitude of a single time series varies with time. But all harmonic functions (also called *sinusoids*) have similar wave shapes, and once the manner in which the magnitude of a harmonic function varies with time is known, any sinusoid is just like any other, except for its three unique and characteristic constants; hence, it may be just as well—and more compactly—expressed in terms of its constants. Moreover, the magnitude-time wave is not a very satisfactory method of representing many—or even several—wave forms which may exist simultaneously in a circuit or system.

36. Amplitude- and Phase-frequency Spectra. In the frequency domain, the simple harmonic function may also be represented by means of its three characteristic constants on a graphical plot in which frequency is the independent variable, and amplitude is the dependent variable on one plot, and phase is the dependent variable on the other. The amplitude-frequency and phase-frequency plots (called a pair of spectra) for a simple harmonic function are shown in Fig. 3. The pair of spectra is capable of conveying all the information for a given harmonic function, like that contained in the time-domain plot of Fig. 2, and can represent much more compactly and systematically the necessary data for each separate harmonic function when many harmonic terms may be required to represent any periodic wave form more complicated than sinusoids.
FIG. 3. Harmonic function plotted against time with its corresponding amplitude- and phase-frequency spectra plots. The spectrum plots convey the same information as does the plot in the time domain.

The middle diagram of Fig. 3 is called the *amplitude-frequency spectrum*, whereas the lower diagram is called the *phase-frequency spectrum*. Since the amplitude, frequency, and phase are all constant for a given sinusoid, the amplitude and phase spectra are represented merely as lines of appropriate length for the specified frequency. The line-spectrum form is especially useful for specifying the characteristics of each harmonic component, particularly when many components are needed to represent a complicated periodic wave. See also Fig. 7.

37. Analytical Expressions for Simple Harmonic Functions. Simple harmonic functions may be regarded as being generated by the projection, on a suitable axis, of a directed quantity (frequently called a *vector*, although the term *phasor* appears to be more appropriate in this application) of constant magnitude E_m, rotating with constant angular velocity ω radians per sec in a positive (counterclockwise) direction, with an initial phase displacement ϕ, as shown in Fig. 4. The projection of one end of the rotating phasor on the x, or real, axis generates the cosine function, whereas the projection of the tip of the phasor on the y, or quadrature, axis (usually designated as the *imaginary* or j axis) generates the sine function.

At any instant, the sine and cosine functions are the rectangular components of the rotating phasor, as expressed by the vector sum

$$E = E_m \cos (\omega t + \phi) + jE \sin (\omega t - \phi)$$

where $j = (-1)^{1/2}$ is an operator having the algebraic value indicated, and geometrically represents rotation of 90 deg (or $\frac{1}{2}\pi$ radians) in the positive or counterclockwise direction. The phasor may also be expressed in terms of its polar components—the amplitude and phase—at any instant, rather than in terms of its rectangular coordinates at the same instant. In polar coordinates,

$$E = |E_m|\underline{/\phi} = (E_{\mathrm{Re}}^2 + E_{\mathrm{Qu}}^2)^{1/2} \underline{/ \tan^{-1} \frac{E_{\mathrm{Re}}}{E_{\mathrm{Qu}}}}$$

In this mode of expression, $|E_m| = (E_{\mathrm{Re}}^2 + E_{\mathrm{Qu}}^2)^{1/2}$ is the amplitude or maximum value of the rotating phasor, expressed in terms of its rectangular coordinates $E_{\mathrm{Re}} = E_m \cos (\omega t + \phi)$ and $E_{\mathrm{Qu}} = E_m \sin (\omega t - \phi)$, whereas the phase angle is also expressed in terms of the rectangular orthogonal components, through the relation $\phi = \tan^{-1} (E_{\mathrm{Re}}/E_{\mathrm{Qu}})$.

Expressions in rectangular form are more convenient when harmonic functions are to be added or subtracted, whereas the polar form is more convenient when sinusoids are to be multiplied, divided, or raised to a power.

38. Exponential Representation of Harmonic Functions. It is shown in elementary textbooks on trigonometry (see, for example, C. I. Palmer, C. W. Leigh, and S. Kimball,
FIG. 4. Generation of harmonic function by means of phasor of magnitude E_m rotating in positive (counterclockwise) direction with constant angular velocity ω. Left, the path of the rotating phasor for four different angular displacements. Right, the harmonic function as generated by projection of the tip of the phasor for different times.

"Plane and Spherical Trigonometry," 5th ed., Chap. XI, McGraw-Hill, 1950) that the expansion for an exponential quantity in complex form is

$$e^{jx} = 1 \pm \frac{(jx)}{1!} \pm \frac{(jx)^2}{2!} \pm \frac{(jx)^3}{3!} \pm \cdots \pm \frac{(jx)^n}{n!} \pm \cdots$$
$$= \left(1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \frac{x^8}{8!} - \cdots\right) \pm j\left(x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \frac{x^9}{9!} - \cdots\right)$$

It is also shown that

$$\cos x = \left(1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \frac{x^8}{8!} - \cdots\right)$$

and

$$\sin x = \left(x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \frac{x^9}{9!} - \cdots\right)$$

It follows that

$$e^{+jx} = \cos x + j \sin x$$
$$e^{-jx} = \cos x - j \sin x$$
$$\cos x = \frac{e^{jx} + e^{-jx}}{2}$$
$$\sin x = \frac{e^{jx} - e^{-jx}}{2j}$$

The term $e^{\pm jx}$ represents a vector of unit magnitude, displaced from its zero or reference position by an angle of $\pm x$ radians.

Now, if $x = \omega t$, where $\omega = 2\pi f$ is the angular velocity of the rotating phasor in radians per second, and if f is the cyclic frequency in cps, the exponential $e^{\pm jx} = e^{\pm j\omega t}$ designates the locus of a circular path of unit amplitude, rotating with angular velocity of ω radians per sec, the positive direction of ω being that for which the phasor rotates in a counter-

clockwise direction. If the exponent is positive, the path is counterclockwise; if it is negative, the path is negative or clockwise.

The phase angle ϕ is taken into account by writing $x = \omega t + \phi$ and the amplitude is accounted for by an amplitude-multiplying factor E. Then,

$$Ee^{j(\omega t + \phi)} = Ee^{j\omega t}e^{j\phi} = E \cos (\omega t + \phi) + jE \sin (\omega t + \phi)$$

represents a phasor of magnitude E rotating in positive or counterclockwise direction, with angular velocity ω radians per sec, and having an initial phase displacement of ϕ radians, as shown in Fig. 5. In the same way, a phasor of magnitude E rotating in the negative or
FIG. 5. Generating simple harmonic function by projecting on a reference axis the end of a phasor rotating with constant velocity about a fixed point. The dashed arrows show the rectangular components of the phasor, of magnitude E_m, represented by solid arrow.
FIG. 6. Harmonic functions may also be generated by the resultant of two equal phasors rotating about a common point with velocities that are equal in magnitude but opposite in direction.

clockwise direction with constant angular velocity of $-\omega$ radians per sec, and having an initial phase displacement of θ radians, is expressed by the relation

$$Ee^{j(-\omega t + \phi)} = Ee^{-j\omega t}e^{j\phi} = E \cos (\omega t + \phi) - jE \sin (\omega t + \phi)$$

In the terminology of exponential functions, the real component represents the cosine function, as given by

$$E \cos (\omega t + \phi) = \text{Re}[Ee^{j(\omega t + \phi)}]$$

and the quadrature or imaginary component represents the sine function as given by

$$E \sin (\omega t + \phi) = \text{Qu}[Ee^{j(\omega t + \phi)}] = \text{Im}[Ee^{j(\omega t + \phi)}]$$

In engineering use, the real component is employed more frequently than the quadrature or imaginary component and the Re notation is understood; when this is the case, the Re notation is usually dropped as superfluous.

In addition to being expressible in terms of a single rotating phasor, harmonic functions may also be represented by a pair of phasors of equal magnitude E having the same initial phase displacement ϕ and having the same absolute value of angular frequency ω but with different sign, and hence rotating in opposite directions. As shown in Fig. 6, the cosine function may be expressed as one-half the vector sum of the oppositely rotating phasors, according to the relation

$$E \cos (\omega t + \phi) = \tfrac{1}{2}(Ee^{j\omega t}e^{j\phi} + Ee^{-j\omega t}e^{j\phi}) = Ee^{j\phi} \left(\frac{e^{j\omega t} + e^{-j\omega t}}{2}\right)$$

By forming the projection of the two vectors on the quadrature axis, the sine function, along the j axis, is expressed as

$$jE \sin (\omega t + \phi) = \tfrac{1}{2}[(Ee^{j\omega t}e^{j\phi}) + (-Ee^{-j\omega t}e^{j\phi})]$$

from which

$$E \sin (\omega t + \phi) = Ee^{j\phi} \left[\frac{e^{j\omega t} - e^{-j\omega t}}{2j} \right]$$

E above is an amplitude function and $e^{j\phi}$ represents a phase displacement. The exponential form of representing harmonic functions may be simplified by combining E and $e^{j\phi}$ to yield a pair of conjugate complex numbers to designate both the amplitude and the phase. This may be done by making use of

$$E' = |E|e^{j\phi} = E_+ + E_- = (A + jB) + (A - jB)$$

With this notation, $E_+ = (A + jB)$ and $E_- = (A - jB)$ are both complex quantities and are the conjugate of each other. The pair of conjugate complex quantities together make up the complex magnitude E, which expresses both the absolute value of the amplitude $|E|$ and the phase displacement ϕ. With such a notation, a rotating phasor may be represented by the simple expression

$$E = E'e^{j\omega t}$$

In this form, the phase angles are incorporated in the expression for E', which is the sum of the two conjugate complex numbers, but the phase angles do not appear explicitly. When required, however, the phase angles may be derived from the complex form of E' since

$$\phi = \tan^{-1} (B/A)$$

The exponential form of representing harmonic functions is particularly useful when the functions are to be differentiated or integrated. The rectangular or polar forms are each easily derived from the exponential form, which contains both sine and cosine functions, and hence the exponential form, when modified, lends itself also quite well to operations of addition and subtraction as well as to multiplication and division.

In the exponential form, the amplitude, frequency, and phase components may be readily separated. At the same time, by making use of a pair of conjugate coefficients, it is possible to combine the amplitude and phase into a pair of conjugate terms which, in the equations, may be handled as a single term. Thus the E coefficients are complex, but they appear in pairs and their sum is a real number. The exponential representation of a rotating phasor includes both the real (or cosine) term and the quadrature (or sine) term, either one of which may be selected merely by choosing the projection on the real or the quadrature axis, respectively.

39. Nature of Harmonic Analysis. By a technique first disclosed by Fourier, any periodic wave form can be analyzed into, or can be synthesized from, a series (which may contain an infinite number of terms) of sinusoids or harmonic functions. The frequencies of the terms in the series are integral multiples of some fundamental frequency, and the amplitudes and phases of the harmonic components—their spectra in other words—are uniquely related to any given wave form. The practical application of the Fourier technique depends, of course, upon being able to determine the amplitude and phase spectra for each and every term in the series representing the given wave form. This technique is accomplished by that branch of mathematics known as *harmonic analysis*. Reciprocally related Fourier transformations in harmonic analysis make it possible to specify a given function either in terms of its amplitude-time function in the time domain, or by means of its amplitude and phase spectra in the frequency domain.

By extension of the Fourier technique, any nonrecurrent phenomena may be considered as the limiting case of periodic phenomena with infinite period. By a limiting process, the methods of harmonic analysis for periodic phenomena may be extended to apply to nonrecurrent or singularity functions. Again, the practical application of the Fourier integral technique depends upon being able to determine the amplitude and phase spectra for the transient phenomena of specified wave form. This is accomplished by generalizing the technique of harmonic analysis, and again suitable transformations may be made from the time domain to the frequency domain and vice versa.

Still further generalization of harmonic analysis makes it possible to characterize a random probability-distribution function by means of a *correlation function* which is equivalent to the power spectrum of the random function.

At the present time a great deal of activity is going on in the development of information theory, in which the theory of probability plays as significant a role as does generalized harmonic analysis, especially as this is applied to stationary time series. We shall limit the treatment here to a brief discussion of Fourier series and integrals, leaving the user of this compendium to refer to specialized texts for treatment of more recently developed and more advanced topics in this field.

40. Fourier-series Analysis. Any recurrent, periodic, single-valued wave form whose nonrecurrent interval is T may be expressed as the sum of a series of sinusoids whose frequencies are integral multiples of the lowest or fundamental frequency $f = T/2\pi$. A constant term, which may be regarded as a harmonic function of zero frequency, may be required in such a series.

As an example of Fourier's method, Fig. 7 shows a rectangular, periodic wave form (top) with the required amplitude spectrum (center) and phase spectrum (bottom).

The general Fourier-series expansion for any periodic function may be written in the alternative forms:

$$e(t) = A_0 + \sum_{n=1}^{\infty} A_n \cos n\omega t + \sum_{n=1}^{\infty} B_n \sin n\omega t$$

$$= \sum_{n=-\infty}^{\infty} C_n e^{jn\omega t}$$

where $n = 0, 1, 2, 3, \ldots, n$ is the order of the harmonic. The amplitudes of successive terms in either and both forms of the series must decrease with increasing harmonic order for the series to converge to a finite limit; this condition is fulfilled for wave forms ordinarily encountered in radio communication.

FIG. 7. Square wave plotted against time with its corresponding amplitude-frequency and phase-frequency plots.

For either of the above expressions to specify a periodic function properly, it is necessary to know the numerical values of the amplitudes of the harmonic functions of the Fourier series, *i.e.*, we need to know the values of A_0, A_n, and B_n, or of C_n for all values of n. To evaluate these coefficients, use is made of the following trigonometric integrals:[1]

1. The average value of a single sine or cosine term, when taken over a complete period, is zero.
2. The average value of the product of two sines or cosines or of a sine and a cosine of commensurable but numerically unequal frequencies, taken over any complete period of the product, is zero.
3. The average value of the product of two sines or cosines of the same frequency, taken over any complete period, is one-half the cosine of the difference between the phases of the two factors. For the product of a sine and cosine, the average is one-half the sine of the angle by which the sine term leads the cosine term.

If $e(t)$ is an arbitrary periodic function of period T, so that $e(t) = e(t \pm T)$, it is expressible as a Fourier series of harmonic functions. If the function $e(t)$ is specified, either analytically or graphically, the Fourier coefficient.

[1] Franklin, P., "Differential Equations for Electrical Engineers," Wiley, 1933.

may be determined from the relations for the line spectrum

$$A_0 = \frac{1}{T}\int_t^{t+T} e(t)\,dt$$

$$A_n = \frac{2}{T}\int_t^{t+T} e(t)\cos n\omega t\,dt$$

$$B_n = \frac{2}{T}\int_t^{t+T} e(t)\sin n\omega t\,dt$$

$$C_n = \frac{1}{T}\int_t^{t+T} e(t)\epsilon^{-jn\omega t}\,dt$$

where $T = 2\pi/\omega$ is the fundamental period, or the period of the lowest frequency or fundamental term. In the above expression, C_n is a complex quantity, related to A_n and B_n by the equations

$$C_0 = A_0 \qquad C_{+n} = \tfrac{1}{2}(A_n + jB_n) \qquad C_{-n} = \tfrac{1}{2}(A_n - jB_n)$$

When the Fourier series represented by $e(t)$ is inserted into the integral expressions for the Fourier line-spectrum coefficients, all terms, when integrated over a complete period, become zero except those for the nth term. Hence, for each value of n it is possible to determine the Fourier coefficients.

Any pair of conjugate terms in C_n specifies an n-term frequency component of the Fourier series, since

$$C_{+n}e^{jnx} + C_{-n}e^{-jnx} = A_n \cos nx + B_n \sin nx$$

The absolute value or magnitude of the nth term is

$$C_n = (A_n^2 + B_n^2)^{1/2}$$

and the phase angle for the nth term is

$$\phi_n = \tan^{-1} B_n/A_n$$

By means of the C_n and ϕ_n terms, the amplitude and phase may be plotted for the nth harmonic to produce a line spectrum which is characteristic of that Fourier series and the wave form it represents. In the exponential form of the expression for harmonic functions, the C_n terms occur in conjugate pairs; from such a conjugate pair, the amplitude and phase of the nth term may be readily derived, but the phase properties do not appear explicitly.

For periodic functions $e(t)$ of period T, the function is analyzed into its line or discrete amplitude- and phase-frequency spectra by means of the relation

$$C_n = \frac{1}{T}\int_0^T e(t)\epsilon^{-jn\omega_1 t}\,dt$$

where ω_1 is the angular frequency (in radians per second) corresponding to the period T (in seconds). The function $e(t)$ is synthesized from its amplitude- and phase-frequency spectra by the transformation

$$e(t) = \sum_{n=-\infty}^{\infty} C_n e^{jn\omega t}$$

41. Average and Effective Values of Periodic Functions. If $e(t)$ is a periodic function of time with period T so that $e(t) = e(t + T)$, the average value of the function over the time interval of a complete period T is

$$E_{av} = \frac{1}{T}\int_t^{t+T} e(t)\,dt$$

The average value of a cyclic function which is symmetrical with respect to the zero axis throughout the cycle is zero. Over any integral number of complete cycles, the average value of a sine or cosine function, therefore, is zero.

In speaking of the average value of a sine or cosine function, the electrical engineer refers to the average value of either the positive or the negative half of the cycle, the

absolute value of which is

$$E_{av} = \frac{1}{\pi}\int_0^{\pi} E_m \sin \omega t\, d(\omega t) = \frac{2E_m}{\pi} \cong 0.6366198 \ldots E_m$$

where E_m is the maximum value of the harmonic function.

In many cases, certain electrical effects are proportional to the square root of the average value of the square of the function throughout the cycle. This value is known as the *effective value*, or the *root-mean-square* (rms) value from the fact that it is found by first squaring the function, determining the mean value of this squared value, and extracting the square root of the mean value to determine the end result.

Thus, in general, the effective value of a function of time $e(t)$ is given by the relation

$$E_{rms} = \left\{\frac{1}{T}\int_t^{t+T} [e(t)]^2\, dt\right\}^{1/2}$$

If the time function is a harmonic function such that $e(t) = E_m \sin \omega t$, the rms value of the function over a complete cycle or period is

$$E_{rms} = \left[\frac{1}{2\pi}\int_0^{2\pi} (E_m \sin \omega t)^2\, d(\omega t)\right]^{1/2} = \frac{E_m}{\sqrt{2}} \cong 0.7071068 \ldots E_m$$

By applying the equation for the effective or rms value to a periodic wave form expressible by the Fourier series,

$$e(t) = E_0 + E_1 \sin (\omega t + \phi_1) + E_2 \sin (2\omega t + \phi_2) + \cdots + E_n \sin (n\omega t + \phi_n) + \cdots$$

the effective value of a periodic recurrent function is given by

$$e(t)_{rms} = [E_0^2 + \tfrac{1}{2}(E_1^2 + E_2^2 + \cdots + E_n^2 + \cdots)]^{1/2}$$

42. Aperiodic Functions. The Fourier series represents a recurrent time function whose energy is represented by a number of discrete and uniformly spaced frequency components, the sum of whose amplitude and phase components constitutes a pair of line spectra. In general, the frequency components of a periodic wave may be expected to be infinite in number, and each is represented by a trigonometric function of time, mathematically defined as existing throughout all intervals of time from $t = -\infty$ to $t = \infty$. Since the wave form thus described by a Fourier series is expressed in terms of functions which are defined as having existed for all values of time, the Fourier series—or its equivalent representation as a pair of line spectra—can be used to represent only steady-state phenomena.

When we come to deal with aperiodic or singularity functions, we find that such functions can be analyzed or synthesized by a process similar to that employed for representing periodic functions, although there are some differences. For aperiodic or transient phenomena, the energy represented by a pair of amplitude and phase spectra must be continuous, whereas they were line spectra in the case of periodic phenomena. There are no recurrent features in an aperiodic function, which, accordingly, may be regarded as the equivalent of a periodic function with infinitely long cycle of recurrence. As the period becomes infinitely long, the frequency separation between the discrete components in the line spectra approaches zero. Accordingly, the aperiodic function will be a continuous function of angular frequency ω rather than a function of discrete frequency intervals $n\omega_1$, where ω_1 is the angular frequency of the lowest-frequency component.

43. Fourier Integral. From the discussion on aperiodic functions, it would seem logical that aperiodic phenomena might be derivable from the Fourier-series expression of periodic phenomena by means of a limiting process in which the series form is, in some way, converted to the integral form.

To see how such a limiting process may be effected first write the expression for the periodic function as

$$e(t) = \sum_{n=-\infty}^{\infty} C_n \epsilon^{jn\omega t} = \sum_{n=-\infty}^{\infty} \left(\frac{C_n}{\omega_1}\right) \epsilon^{jn\omega t}\omega_1$$

where, now, ω_1 is used to designate the frequency interval between the successive discrete frequency components. If T is the period, f_1 the fundamental frequency in cps, and ω_1 is fundamental angular frequency in radians per second, then $T = 2\pi/\omega_1$, and a complete cycle of recurrent phenomena occurs between the limits of $T = -\pi/\omega_1$ and $T = +\pi/\omega_1$. Hence, the expression for the amplitude and phase spectra may be written as

$$C_n = \frac{1}{T}\int_t^{t+T} e(t)\epsilon^{-jn\omega_1 t}\,dt = \frac{\omega}{2\pi}\int_{-\frac{\pi}{\omega}}^{\frac{\pi}{\omega}} e(t)\epsilon^{-jn\omega_1 t}\,dt$$

In the limiting process, as $T \to \infty$, it follows that $f_1 \to 0$ and $\omega_1 \to 0$. Moreover, since $C_n \propto 1/T$, the amplitudes of any given harmonic components approach zero as the period approaches infinity, although the ratio C_n/ω_1 may be expected to approach a finite limiting function as the period increases to infinity. No matter what the line spacing ω_1 may be, since n is an integer it follows that the spacing between successive spectral lines, or the frequency increment between successive lines, is equal to the lowest or fundamental frequency, and we may write $\Delta(n\omega_1) = \omega_1$. With this notation $e(t)$ takes the form

$$e(t) = \sum_{n\omega_1=-\infty}^{\infty} \left(\frac{C_n}{\omega_1}\right) \epsilon^{jn\omega_1 t}\,\Delta(n\omega_1)$$

and the function representing the amplitude and phase as a function of frequency becomes

$$\left(\frac{C_n}{\omega_1}\right) = \frac{\omega_1}{2\pi}\int_{-\frac{\pi}{\omega}}^{\frac{\pi}{\omega}} e(t)\epsilon^{-jn\omega_1 t}\,dt$$

Now, to effect the limiting process, let $T \to \infty$, $\omega_1 \to 0$, $n \to \infty$, and $(n\omega_1) \to \omega$. Also, in the limit, we define $\Delta(n\omega_1) = d\omega$ and also $(C_n/\omega_1) = C(\omega)$. When such a limiting process is effected, the aperiodic function is expressible by

$$e(t) = \int_{-\infty}^{\infty} C(\omega)\epsilon^{j\omega t}\,d\omega$$

where

$$C(\omega) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e(t)\epsilon^{-j\omega t}\,dt$$

By suitable transformations, $e(t)$ may be transformed into $C(\omega)$ and vice versa. Thus,

$$C(\omega) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \epsilon^{-j\omega t}\,dt \int_{-\infty}^{\infty} C(\omega)\epsilon^{j\omega t}\,d\omega$$

and

$$e(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \epsilon^{j\omega t}\,d\omega \int_{-\infty}^{\infty} e(t)\epsilon^{-j\omega t}\,dt$$

The above expression for $e(t)$ is called the *Fourier integral* representation of the function $e(t)$, or the *inverse transform* of $C(\omega)$. The expression for $C(\omega)$ is the *Fourier transform* of $e(t)$ because it transforms a time function $e(t)$ into its equivalent frequency function $C(\omega)$. The expression for $e(t)$ synthesizes a given time function from its amplitude and phase spectra, which are now continuous functions of frequency; it represents the function in the time domain. The expression for $C(\omega)$ represents the

function in the frequency domain and analyzes the given function in its amplitude and phase spectra. The two equations may also be regarded as representing a pair of integral equations and their solutions.

44. Random Functions. Random functions are devoid of any fixed or precisely predictable relationships between the dependent and the independent variables. Therefore, it is not possible to write an expression for the amplitude of a random function. It is possible, however, to state the probability with which the amplitude will lie between two specified values of the dependent variable for some value of the independent variable. Random functions are treated analytically by means of statistics, which is based on the theory of probability.

45. Noise. In an acoustic sense, noise may be defined as any extraneous sound tending to interfere with the proper and easy perception of those sounds or signals which it is desired to receive. In this sense any undesired signal may be regarded as noise when mixed with the desired signal. Many disturbances of an electrical nature produce noise in radio receivers, so that the term has a much broader connotation in communication engineering than that given by the above definition. More generally, then, noise may be defined as some random process which modifies the signal in a predictable manner. The principal effect of noise is to interfere with the desired signal and make it less easy to perceive; it limits range and sensitivity.

Noise in radio systems may be of two general kinds. *Random noise* is noise due to a large number of individual, but not necessarily identical, overlapping disturbances, whose occurrence has no specifiable regularity. Nonrandom noise is noise that exhibits more or less definite regularities and hence assumes more nearly the character of interference from some other signal.

An important property of random noise is that the addition of two or more random-noise signals produces a resultant random-noise signal whose power is equal to the sum of the power of each of the component noise signals. Power, in this sense, is defined as the integral of the square of the amplitude.

Random noise includes that due to: (1) shot noise, resulting from fluctuations in electron emission in circuits involving thermionic emission; (2) incidental noise of atomic origin in electron tubes, including that due to ionization, production of secondary electrons, emission of positive ions, and fluctuations in these phenomena; (3) flicker noise, resulting from variations of the total space current in a thermionic emitter, as a result of changes in evaporation, diffusion, chemical action, structural rearrangement, and gas-ion bombardment throughout areas of the cathode surface which are large compared with that involved in the emission of a single electron; (4) "static" electrical charges, atmospherics, and interstellar noise and interference; (5) contact or breakdown noise, resulting from the breakdown of insulation, or the making and breaking of minute electrical conducting paths in components of the system; (6) dirt and grain-size noise, which are attributable to minute irregularities in the structure of equipment or components, and which may be innate in the materials employed, or developed in processing or handling.

Nonrandom noise is not of random nature and has characteristic wave shapes of its own. Nonrandom noises that may be encountered in electrical-communication systems include: (1) noise from rotating or vibrating electrical equipment, *e.g.*, motor commutators, electric razors, and vacuum cleaners; (2) ignition noise from ignition systems; (3) hum from electric power lines, of fundamental and harmonic frequencies; (4) extraneous signals, such as harmonics of stations operating at a submultiple frequency of that to which the receiver is tuned, or signals from stations operating at "sum and difference" frequencies of local oscillators within radio receivers; (5) noise due to some irregularity that is periodic at the frequency of rotation of mechanical equipment, commonly called "wow"; (6) mechanical vibrations of components in the radio receiver, commonly called "microphonics"; (7) feedback and oscillation within the system, called "howl" when occurring at an audio frequency, or "motorboating" when occurring at a subaudible frequency; (8) spurious responses of the equipment, and other noises.

46. Information Theory. Since the beginning of the Second World War, considerable progress has been made in the development of a theory of information which takes full cognizance of the unpredictability of messages, and applies probability

theory to the specification of messages. Progress in this field has been so rapid and so extensive that only the most elementary highlights can be set forth here.[1]

Communication is carried on by the successive selection and arrangement of prearranged or generally understood physical symbols. In a manner that depends upon the properties of the communication system, such signals are produced by the sender and are brought to the attention of the receiver. The proper selection and sequential arrangement of such symbols or signals are capable of conveying intelligence in accordance with the meanings attached to the symbols. Since a sequence of symbols is required to convey information, it is evident that one of the characteristics of intelligence is that it may be expressed as a single-valued time function. From a practical point of view, this is a most fortunate result, for it is this characteristic property of intelligence that permits information to be transmitted economically by electrical means.

In the process of communication, it is clear that two entirely distinct operations are involved. One of these deals with the proper selection and sequential arrangement of the physical symbols; the other deals with the meanings attached to the symbols. Information theory is concerned with the first of these two phases and with such matters as definitions and measurement of information, the philosophy of information, random processes, probability theory, correlation, prediction, filtering, storage, modulation, and like topics, all of which are equally valid without regard to the meanings attached to the symbols of communication. It is this phase of the broad topic with which communications engineers are primarily—if not exclusively—concerned. That phase of communication dealing with the meanings attached to the symbols is, in fact, semasiology, which is the province of semanticists and linguists.

Information is conveyed by the successive selection and arrangement of a number or sequence of symbols; it is measured by the number of symbols needed to convey the desired idea or intelligence. Fundamental to the concept of information is the idea that, prior to its reception, any message is uncertain; the more uncertain we are about the composition of the message, the greater will be the amount of information needed to remove the uncertainty regarding the unpredictability as to what has been sent. It is, therefore, the unpredictable nature of the message that makes it convey information. According to this point of view, whatever their source, messages are regarded as random time-varying functions. It is usually assumed that the statistical character of the random time functions remains invariant with time.

To be useful in electrical communication, any measure of information must be correlated with the notion that the amount of information increases as the number of selections or choices from a set of possibilities is increased. The simplest possible choice is the selection between two equally likely choices. It appears reasonable, therefore, to define the unit of information—the amount, not the meaning—in terms of such equally likely selections between M possibilities. We also recognize that n independent selections (*i.e.*, selections which do not affect one another) of this type constitute n units of information. Hence the basic unit of information is defined as the amount of information associated with a single selection between M equally likely choices; invariably the choice is made between only two possibilities at one time, and for such a binary choice, of course, $M = 2$. The name "bit" from "binary digit" has been almost universally adopted to designate the unit of information, although the term "binit," having the same derivation, has also been suggested.

When a selection is made from M choices, not necessarily equally likely, we shall say that an M-order selection has been made. It will be convenient at times to retain this generality, although nearly all work in information theory has dealt with binary selections for which $M = 2$. When a series of n selections is made in M-order

[1] For fuller details, the reader is referred to "A Bibliography of Information Theory (Communication Theory—Cybernetics)," by F. L. Stumpers (published Feb. 2, 1953, by the Research Laboratory of Electronics, M.I.T., Cambridge, Mass.), listing approximately 800 contributions under a dozen different headings. For subsequent work, the reader is referred to the "Symposia of Information Theory" issued annually by the Institute of Radio Engineers.

selections, we say that an n-order choice has been made. When the choices are, a priori, equally likely, the selection is called an equally likely selection.

To illustrate the relationship between information and a sequence of selections, consider the diagram of Fig. 8 in which, proceeding from left to right, an M-order selection is made at each choice, and there are n choices. In the diagram shown, we deal with binary selection, so $M = 2$, and there are four sequences, so that $n = 4$. Beginning at the initial point, in the first step we make a selection between two alternatives (a 0 or a 1) which lead to either the top or the bottom half of the remaining portion of the diagram. In the second choice, we select an upper (0) or lower (1)
FIG. 8. Relationship between information and a sequence of selections. At each step the number of possible selections or choices is 2 ($M = 2$); the number of sequence steps is designated as n. The total number of possible sequences is $c = M^n$.

group in the half previously chosen. In the third choice we select an upper (0) or lower (1) subgroup in the group previously chosen, and so on until a final selection has been made from n possibilities. A new unit of information is added each time a choice is made, for the selection excludes all irrelevant possibilities and more accurately and definitely specifies a given selection, thereby removing some uncertainty regarding the message. As the number of choices increases linearly, the number of possibilities from which a selection is possible increases geometrically, or in an exponential sense. Hence, if c is the total number of possible sequences in an M-order selection with n choices all being equally probable, then

$$c = M^n$$

If information increases linearly with the number of selections, which is in accordance with our intuitive feeling, the quantity of information H must be dependent upon c in such a way that

$$H = f(M^n) = f(c)$$

The amount of information H is linearly related to the number of selections n if the function f is such that

$$H = n \log M = \log c$$

In this case of binary selection ($M = 2$) we have been able to select any one of

$$c = 16 \text{ possibilities}$$

all equally likely, with $n = 4$ choices. Since four selections were required, we have 4 bits of information represented by the process described and shown in Fig. 8.

The base of the system of logarithms has not been stated in the result given above. This is not of fundamental importance, because logarithmic measurements in either of two systems of measurement (or to either of two bases) differ merely by a constant, which can easily be taken into account by a proportionality factor. The selection of a base is, then, largely a matter of convenience. The simplest results obtain when logarithms to the base M are used, for in this case $\log_M M = 1$, and for the case under discussion, then $H = n$.

The result given above is strictly true for binary selection if M is a power of 2; in such a case H then becomes an integer. If M is some number other than a power of 2, then, for binary selections, the number of elementary selections required to specify the desired choice will not be an integer; it will be a number equal to the logarithm of either the next higher or the next lower power of 2. The corresponding amount of information must, accordingly, lie between these two limits, and we must then determine the significance of amounts of information H which are not expressible by integers. The equation given above is correct, even for nonintegral values of H (that is, for M not a power of 2) provided we regard and interpret H to be the average value of the information conveyed by a large number of selections, all of which are equally likely, rather than the total information as given above.

In dealing with long messages in which many choices are made, it is often convenient to have a quantity that represents the average amount of information per M-order selection rather than, as has been done above, to determine the total amount of information corresponding to the whole message or total number of sequences of selections. The average information H_{av} may be defined as the total amount of information given by a very long message H divided by the number of choices n in an M-order selection. When all the selections in the message are equally likely and independent and when, in addition, M is a power of 2, the quantity H_{av} is just equal to the information actually given by each selection, that is,

$$H_{av} = \frac{1}{n} \log_2 c = \log_2 M$$

If M is not a power of 2, this equation represents the average amount of information taken over a very long sequence of selections.

It is now necessary to take into account the probability that certain messages or selections are made, for messages having a high probability of being chosen will require fewer selections than messages having a low probability of being chosen. Furthermore, we feel instinctively that a message of low probability—and hence more selections—contains more information than a message of high probability requiring few selections.

To obtain a mathematical expression for this state of affairs, let $P(i)$ be the probability of the ith message. The number of binary selections required to convey such a message will be some integer $B_S(i)$ whose magnitude will be close to $-\log_2 P(i)$. But $P(i)$ is the probability of making a selection in the last subgroup through a process of successive halving the entire ensemble of messages $B_S(i)$ times, as already described. In other words, for a relatively short or small number of selections, $P(i) \cong 2^{B_S(i)}$, and by making the number n of M-order selections sufficiently large, the percentage difference between $-\log_2 P(i)$ and $B_S(i)$ can be made as small as we choose. In the limiting case of an infinite number of selections (*i.e.*, $n \to \infty$),

$$B_S(i) = -\log_2 P(i)$$

Consider now a sequence of Q selections of messages, each message of which is assumed to consist of n M-order selections so that the total sequence represents nQ selections. If the number Q is made sufficiently large, the ith message in the sequence will have a frequency as close to $P(i)$ as we may choose. The average number of binary selections required to select one message will be the mathematical expectation of B_S, or $E(B_S)$. If c is the number of different sequences that can be formed, then

$$E(B_S) = -\sum_{i=0}^{c-1} P(i)B_S(i)$$

The average amount of information produced by each M-order selection is then the ratio of the expectation of B_S to the number of selections n as $n \to \infty$. That is,

$$H_{av} = \lim_{n\to\infty} \frac{E(B_S)}{n} = \lim_{n\to\infty} -\left(\frac{1}{n}\right)\sum_{i=0}^{c-1} P(i)\log_2 P(i)$$

This limiting process yields[1] a result for the average amount of information per M-order selection of

$$H_{av} = -\sum_{k=0}^{M-1} p(k)\log_2 p(k)$$

where $p(k)$ is the probability of the kth choice of M, and n_k is the number of times the kth choice is selected in the ith message of n selections. A negative sign is used here because, although the average amount of information per M-order selection is positive, the individual probabilities are less than unity, so that their logarithms are negative numbers; these are transformed into positive numbers by the minus sign.

47. Band Width and Noise. A practical problem in communication theory has to do with the rate at which a function to be transmitted should be sampled so that it may retain its essential characteristic information. Or we may wish to know how many amplitudes must be distinguished from one another so that the communication system serves its intended purpose adequately. An infinite number of amplitudes may be theoretically desirable, but in general this requires an infinite band width and can be achieved only in the absence of noise. Such ideal conditions are not encountered in practice. The number of distinguishable amplitudes is limited by the amount of noise, or, more correctly, by the ratio of signal-to-noise power. Furthermore, practical or economic or legal factors may dictate an upper band width so that we are forced to transmit and receive a function that differs somewhat from the original signal.

The band width of the transmission system is related to the number of samplings we can make of the original signal per unit time. If we are limited to a transmission band width of f_B cps, this band width will be fully needed when the original signal is sampled at instants spaced $1/2f_B$ time units (seconds) apart.

That is,[2] the specification of an arbitrary wave of duration T and maximum frequency component f_B requires $2f_BT$ measurements; the Fourier series yields $2f_B$ coefficients and an upper frequency limit of f_B cps.

If the average random noise power is N, and if the average signal power is S, then $(S + N)$ will be the average total power of signal and noise when both are mixed. The effective values of the amplitudes are the square roots of the respective power values. Therefore, the ratio of the total power to noise power is $(S + N)/N$, and the ratio of the amplitudes of signal and noise to noise is

$$\frac{\sqrt{S+N}}{\sqrt{N}} = \sqrt{\frac{S+N}{N}} = \left(1 + \frac{S}{N}\right)^{1/2}$$

[1] Fano, R. M., "The Transmission of Information," *Technical Report*, 65, M.I.T. Research Laboratory of Electronics.

[2] Bennett, W. R., Time Division Multiplex Systems, *Bell System Tech. J.*, **20** (2), 199, April, 1941.

If it is assumed (as is true to a close approximation) that a change in signal amplitude cannot be instantly recognized when it is less than the noise amplitude, whereas a signal may be recognized if its amplitude is equal to or greater than that of the noise, then the number of distinguishable signal amplitudes in the presence of noise is

$$\delta = k\left(1 + \frac{S}{N}\right)^{1/2}$$

where the factor k depends at least in part on system reliability, but is often in the vicinity of unity.

If the function containing signal and noise is sampled every $1/2f_B$ sec, then in time T there will be $2f_B$ samplings, as well as a like number of amplitudes of the function which are independent of each other. It follows that the number of distinct signals in T sec from which one makes a choice under the stated conditions is

$$\delta^{2f_BT} = k\sqrt{\left(1 + \frac{S}{N}\right)^{2f_BT}} = k\left(1 + \frac{S}{N}\right)^{f_BT}$$

The amount of information—the number of bits—sent in time T, when the band width of the communication facility is f_B in the presence of a signal-to-noise power ratio of S/N, will be

$$H = \log_2 \delta^{2f_BT} = kTf_B \log_2\left(1 + \frac{S}{N}\right)$$

Compare this result with Hartley's law, which states that the amount of information transmitted over a channel of band width f_B cps when used for T sec is proportional to the product of the band width and the transmission time, or $H = kTf_B$.

Before proceeding, let us interpret the significance of the expression above. This equation shows that, in the presence of a given noise power N, the total quantity of information that may be transmitted depends upon a number of factors. If these are independently variable, we have a certain amount of freedom in designing the communication system to convey a given amount of information in the presence of a stated amount of noise. In other words, in the presence of a given noise power, the total quantity of information may be kept constant, even though the individual factors comprising the information may be varied. That is, to transmit a specified quantity of information in the presence of a given amount of noise, the band width, transmission time, or signal power may be changed, within limits, to yield the most satisfactory communication circuit. To increase the amount of information transmitted, it is most effective to increase f_B or T, since H is directly proportional to band width or transmission time. However, if there are restrictions on f_B and T, we may still achieve some gain by increasing the power of the signal. The gain in information transmitted by multiplying the signal power by a certain factor is less than that obtained by multiplying either the band width or the time of transmission by the same factor.

The above equation shows that we can increase the amount of information by: (1) increasing the band width, (2) increasing the time of transmission, (3) increasing the signal power, (4) decreasing the noise power, or (5) increasing the signal-to-noise power ratio.

The relations between band width, transmission time, and signal power of signals transmitted in the presence of noise have been investigated by Tuller,[1] who shows the fallacies of earlier concepts of information transmission.

The type of communication system considered by Tuller is one in which the frequency band width of the transmission link f_c is wider than the frequency band width of the over-all communication system f_B or at least is different from it, in general. Moreover, N is the rms amplitude of the noise when this becomes mixed with the signal, and C is the maximum signal amplitude, measured before nonlinear operations in the receiver, such as detection.

[1] Tuller, W. G., Theoretical Limitations on the Rate of Transmission of Information, *Proc. IRE*, **37** (5), 468, May, 1949. Also doctoral thesis, Department of Electrical Engineering, M.I.T., June, 1948.

With these symbols, the quantity of information to the input of the receiver is

$$H_{\text{in}} = 2kTf_c \log\left(1 + \frac{C}{N}\right)$$

whereas the amount of information at the output of the system is

$$H_{\text{out}} = 2kTf_B \log\left(1 + \frac{S}{N}\right)$$

where k is a proportionality constant. The fact that the receiver cannot add any information but may lose some information establishes the relationship $H_{\text{out}} \leqq H_{\text{in}}$, which, in terms of the symbols used above, yields the general result

$$\left(1 + \frac{S}{N}\right) \leqq \left(1 + \frac{C}{N}\right)^{f_c/f_B}$$

In a circuit in which there is little noise, $S/N \gg 1$ and $C/N \gg 1$ and the general result may be simplified to

$$(S/N) = (C/N)^{f_c/f_B}$$

Now, $(1 + S/N) = s_{\text{out}}$ must be the number of possible allowed states of the receiver output at any one time, and $(1 + C/N) = s_{\text{in}}$ is the number of possible allowed states at the receiver input for any one instant, so that the general result may be expressed as

$$s_{\text{out}} \leqq (s_{\text{in}})^{f_c/f_B}$$

For coded transmission equality in the above expression can be achieved, in which case

$$\left(1 + \frac{S}{N}\right) = \left(1 + \frac{C}{N}\right)^{f_c/f_B}$$

whereas for uncoded transmission

$$\left(1 + \frac{S}{N}\right) \leqq (f_c/f_B)\left(1 + \frac{C}{N}\right)$$

The results show that wide-band modulation systems using uncoded transformations are inherently inefficient in their spectrum utilization, and that coding may be used as desired to gain in one parameter at a sacrifice in some other or others, without loss in efficiency.

Finally, we may note that channel capacity in a communication system has been defined as the time rate at which information may be transmitted; thus, if κ is the channel capacity, then in terms of the symbols already used,

$$\kappa = \frac{H}{T} = kf_c \log\left(1 + \frac{S}{N}\right)$$

Thus channel capacity depends upon band width and upon the signal-to-noise ratio.

48. Ideal and Distortionless Transmission. It is desirable that the transmission and energy conversions in a communication system, from transmitter to receiver, be carried out so that, on the whole, the system is free from defects and distortions that prevent it from re-creating essentially the subjective sensations, impressions, or effects at the receiving end that were initially produced at the transmitter. Distortion may be produced by noise or by a change in wave form and may prevent this desirable objective from being realized. Distortion defects are most easily observed in terms of deviations from the original signal, and the original signal can be perfectly reproduced at the receiving end only by a system having ideal over-all transmission.

We may define perfect or ideal transmission as that for which the intelligence function re-created at the receiver is identical in all respects to the originally produced information function at the transmitter. The condition imposed on ideal transmission

systems may thus be expressed mathematically by the relationship

$$i_2(t) \equiv i_1(t)$$

The extent to which $i_2(t)$ at the receiving end differs from $i_1(t)$ at the transmitting end is a measure of the over-all deviation from the conditions of ideal transmission.

The requirement for ideal transmission, as given above, is more stringent than is usually necessary or economically feasible. Although perfect transmission is never precisely achieved, and does not need to be, nevertheless the concept of perfect transmission as defined above is exceedingly useful in establishing a criterion by which the performance of any communication system may be judged against the theoretically ideal goal.

For engineering purposes, the concept of distortionless transmission is a more useful one than perfect or ideal transmission. For distortionless transmission, the communication system should produce at the receiving end the same wave form (*i.e.*, the same intelligence-time function) as that originally produced at the transmitting end. Distortionless transmission allows for the finite time of passage of the signal through the transmission medium; usually it also allows for a change in scale or magnitude. Thus, for distortionless transmission, we may establish the criterion that

$$i_2(t - t_d) \equiv Ai_1(t)$$

where A is a scale or magnitude factor, and t_d is the time required for the signals to be transmitted.

Distortionless transmission differs from ideal transmission in that the sensation-perceived energy at the receiver may be greater than, equal to, or less than the corresponding energy at the transmitting end, suitable corrections being made, when necessary, by amplification or attenuation at the receiver. The received signal is also subject to a time delay or time displacement, since transmission does not occur instantaneously. Provided it is not excessive, a finite time of delay is usually no hindrance in most communication systems, but (as shown in Sec. 49) the time delay for the various frequency components of a complex signal must be properly related if the wave form of the signal is to remain unchanged. In some radio systems, of which radar is a notable example, the time delay for transmission is used to good advantage; in other systems—such as tape recording—the time delay may be very great before the signal is re-created.

49. Spectrum Response of Distortionless System. If we establish the criterion for distortionless transmission, as developed in Sec. 48, the spectrum response of a distortionless system can be easily derived. In making the following derivation, it is assumed that the system, as a whole, is linear, so that an output voltage or current of a signal is directly proportional to the input voltage or current that produced it. It is also assumed that the output of the system depends only upon the character of the input signal and the characteristics of the transmission properties of the system.

Assume an arbitrary input voltage whose value is expressed by the Fourier integral

$$e_1(t) = \int_{-\infty}^{\infty} C(\omega)e^{j\omega t}\,d\omega$$

where $C(\omega)$ specifies the amplitude and phase properties of the system. The term may be written as

$$C(\omega) = G(\omega)e^{j\phi(\omega)} = \frac{1}{2\pi}\int_{-\infty}^{\infty} e_1(t)e^{-j\omega t}\,dt$$

if $G(\omega)$ is the amplitude spectrum and $e^{j\phi(\omega)}$ is the phase spectrum of the input signal. This signal $e_1(t)$ is passed through the system, during which it will be delayed by a time interval τ and will be subject to modifications in its amplitude and phase spectra by an amount depending upon the over-all system transmission characteristics. Let $\tau(\omega) = A(\omega)e^{-j\theta(\omega)}$ be the over-all transmission properties of the system, in which $A(\omega)$ is the amplitude spectrum and $e^{-j\theta(\omega)} = \underline{/-\theta(\omega)}$ is the phase spectrum of the system.

Now, if $Y_{12}(\omega)$ is the transfer admittance of the over-all system—which may be resolved into its amplitude and phase spectra—then the output current $i_2(t)$ as a result of input voltage $e_1(t)$ is

$$i_2(t) = \int_{-\infty}^{\infty} C(\omega) Y_{12}(\omega) e^{j\omega(t-\tau)}\, d\omega$$

and the output voltage is

$$e_2(t) = \int_{-\infty}^{\infty} C(\omega) T(\omega) e^{j\omega(t-\tau)}\, d\omega$$

where $T(\omega) = Y_{12}(\omega) Z_R(\omega)$, if Z_R is the load impedance across which $e_2(t)$ appears at the receiving end of the system.

The output voltage may also be written in the form

$$e_2(t) = \int_{-\infty}^{\infty} [G(\omega) A(\omega)] e^{j[\omega(t-\tau)+\phi(\omega)-\theta(\omega)]}\, d\omega$$

The first term in brackets is the amplitude spectrum, and the second term, in the exponent, is the phase spectrum. Instead of grouping all the amplitude terms together and then all the phase terms together for the entire system, we may separate the amplitude and phase characteristics of the original signal from the amplitude and phase characteristics of the transmission path. Thus the output voltage may also be written as

$$e_2(t) = \int_{-\infty}^{\infty} [G(\omega) e^{j\phi(\omega)}] e^{j\omega t} [A(\omega) e^{-j[\omega\tau - \theta(\omega)]}]\, d\omega$$

where the first term in brackets is the amplitude and phase spectrum of the original signal, and the second term in brackets specifies the modifications of the amplitude and phase spectra of the signal due to the transmission properties of the system.

If the received signal is to be free from distortion introduced by the communication system, the second pair of brackets should equal unity. This requires that

$$A(\omega) = 1 \quad \text{and} \quad \theta(\omega) = -\omega\tau$$

In practice, as outlined in Sec. 48, we merely require $A(\omega) = k$ (a constant) since it may be desired to have the received signal amplified or attenuated to a value different from that of the original signal.

These results show that, for distortionless transmission, the amplitude spectrum of the transmission circuit should be a constant, independent of frequency, whereas the phase spectrum should have a phase shift proportional to frequency over a frequency range of $-\infty$ to ∞. When these conditions are fulfilled, the reproduced signal is delayed by an amount τ from that of the original signal.

If $A(\omega) = k$ and $\theta(\omega) = -\omega\tau$ are inserted into the above equation for $e_2(t)$, the received signal becomes

$$\begin{aligned} e_2(t) &= k \int_{-\infty}^{\infty} [G(\omega) e^{j\phi(\omega)}] e^{j\omega(t-\tau)}\, d\omega \\ &= k e_1(t - \tau) \end{aligned}$$

Hence the received signal will have its amplitude proportional to that of the original signal, and its reception will be delayed by a time interval $t - \tau$, but otherwise the original and reproduced signals will have the same wave form.

50. Distortion. In a broad sense, distortion is a change in wave form between an original wave and its re-created wave form. Several types of distortion are possible, at least some of which can be readily explained in terms of a simple sinusoid, expressible in terms of its amplitude, frequency, and phase.

In a linear passive system, *amplitude distortion* (sometimes called frequency distortion) is that form of distortion in which the relative magnitudes of the different frequency components are not constant, although the phase shift is linearly related to frequency.

Phase or *delay distortion* occurs when the phase angle of the system is not linearly related to frequency within a desired range, so that the time of transmission or the

delay time varies with frequency, even though the amplitude is constant for all frequencies within the specified range.

Amplitude and phase distortion may be present simultaneously in a system.

Nonlinear distortion is that form of distortion which occurs when the rms values of the voltage or current at the output of a system or portion of a system are not linearly proportional to the corresponding rms values of the input voltage or current. Nonlinear distortion occurs in nonlinear systems or elements, not in linear systems or elements.

Other types of distortion may exist, but those enumerated above are the most common.

51. Logarithmic Measurements. In communication engineering, considerable advantage is taken of the fact that an exponential or a logarithmic relation exists between variables. For example, many subjective sensations are estimated to be roughly proportional to logarithmic functions of the physical stimuli producing them. That is, if the physical stimulus is increased geometrically, the apparent subjective sensation produced by it appears to increase arithmetically.

The fact, however, that a subjective sensation appears to be approximately logarithmically related to the stimulus producing it is but a convenient, simple, and rough approximation in almost all cases. The correlation between subjective sensations and physical stimuli is exceedingly complicated, influenced by many environmental factors and techniques of measurement and evaluation. Nevertheless, a logarithmic relation is more nearly correct than a linear one and is a sufficiently good approximation in many cases to serve as a justification for the adoption of logarithmic units. They not only provide a useful (if approximate) relation between subjective sensations and physical stimuli but are also convenient in computation. A number of logarithmic units—particularly the *decibel*—have been found to represent such useful and convenient concepts that they have been improperly (and sometimes ridiculously) extended to fields in which they cannot apply.

The *bel*, named in honor of Alexander Graham Bell, is defined as the common logarithm of the ratio of two powers P_1 and P_2. Thus

$$\text{No. of bels} = N_b = \log_{10} (P_2/P_1)$$

If P_2 is greater than P_1, N_b will be positive (representing a gain in power); if $P_2 = P_1$, N_b will be zero; if P_2 is less than P_1, N_b will be negative and will represent a loss in power.

A smaller and more convenient unit, the decibel (db), has been established for engineering work. The magnitude of the *decibel* is one-tenth of a bel. The number of decibels required to express the change in power level from P_2 to P_1 is

$$\text{No. of db} = N_{db} = 10\ N_b = 10 \log_{10} (P_2/P_1)$$

A change of 1 db in acoustic power is just about the change in power level that can be detected.

Another logarithmic unit called the *neper* is defined as one-half the natural logarithm of the ratio of two powers. Thus

$$\text{No. of nepers} = N_n = \tfrac{1}{2} \log_e (P_2/P_1)$$

where e is the base of the natural system of logarithms and has the approximate value $e = 2.7182818285 \ldots$.

The relationships between the same power ratios when expressed in three systems are

$N_n = \frac{1}{2}(\log_e 10)N_b = 1.151292546 \ldots N_b$	or	1 bel = 1.151 nepers
$= \frac{1}{20}(\log_e 10)N_{db} = 0.1151292546 \ldots N_{db}$	or	1 db = 0.1151 neper
$N_{db} = 10N_b$	or	1 bel = 10 db
$= 20(\log_{10} e)N_n = 8.68588964 \ldots N_n$	or	1 neper = 8.686 db
$N_b = \frac{1}{10} N_{db}$	or	1 db = 0.1 bel
$= 2(\log_{10} e)N_n = 0.8685889 64 \ldots N_n$	or	1 neper = 0.8686 bel

These terms express only the ratio of power terms, and the number of units is not an expression for an absolute value of power. By assigning some value of power P_1

selected as the *reference level*, it is possible to ascertain an absolute value of power for any numerical expression in any of the three systems mentioned above. Values of 6, 10, and 100 mw have been used at the reference power level at different times and by different groups, so that the reference level should always be specified as well as the numerical units for a given change in power level. P_2/P_1 is always a numeric expressing an increase or decrease in power level and a given number of decibels or nepers cannot be used as an expression for an absolute value of power. When decibels are so used, some given value for P_2 or P_1 is implicit.

Because power in an electric circuit may be expressed in terms of either voltage or current and resistance, it is possible for any of the above expressions to take the general form (but not the exact value)

$$N = \log \frac{P_2}{P_1} = \log \frac{I_2^2 R_2}{I_1^2 R_1} = \log \left(\frac{E_2^2/R_2}{E_1^2/R_1}\right)$$

When a change of power level is expressed in terms of resistance and either current or voltage, it is generally necessary to express or specify the values of R_1 and R_2 with which I_1 and I_2 or E_1 and E_2 are associated. Only in the special case for which $R_2 = R_1$ does neglect of the values of the resistance introduce no error. It is common, if regrettable, practice, however, to overlook the values of the resistances when specifying power-level ratios in terms of voltages or currents.

The *volume unit* (*vu*) is defined as ten times the common logarithm of the ratio P_2/P_1, where P_1 is 1 mw (0.001 watt). If P_2 is expressed in watts,

$$\text{No. of vu} = N_{\text{vu}} = 10 \log_{10} (P_2/0.001) = 30 \log_{10} P_2$$

Since the reference level is specified in the definition of the volume unit, this term can be properly used to express either a change in power level or an absolute value of power.

The *phon* is a unit of loudness level. The level of a sound in phons is numerically equal to the intensity level (in decibels) of a pure 1,000-cps tone, which is judged by the listener to be of equivalent loudness. In establishing the unit for the phon, zero reference level is taken as the average limit of audibility at 1,000 cps; this has been standardized as 10^{-16} watt per sq cm, or a sound-level intensity of 0.000204 dyne per cm. Since the phon is a unit representing a subjective sensation, its value is directly affected by the average characteristics of the normal human ear. The number of phons representing a given sound-intensity level is, in general, different for each frequency and varies in a manner depending upon the sensitivity of the normal human ear, as shown in Fig. 10.

PSYCHOPHYSICAL RESPONSES AND THE COMMUNICATION SYSTEM

52. Man and His Environment. Man's knowledge of the universe is the combined result of impressions gained from physical stimuli to one or more of his senses, and the thought processes used to evaluate these impressions.

Man's visual response is to electromagnetic energy lying between about 400 and 750 millimicrons ($m\mu$) in wavelength corresponding to spectral colors from violet through blue, green, yellow, orange, to deep red. The eye is not uniformly sensitive in this range but has maximum sensitivity at about 554 $m\mu$, corresponding to the green portion of the spectrum. The color sensitivity of the eye also depends upon the intensity of the radiation and is different for very low light levels than for levels normally encountered in daylight.

Man's two eyes, separated by the interpupillary distance (about 2.5 in. or 10 cm), see slightly different images, which are combined in the brain to yield a single interrelated impression. The sensations produced by two different images enable man to perceive depth or a third dimension through stereoscopic vision. Stereoscopic visual effects are not usually employed in electrical communication.

If the visual images are seen in color, the eye is able to make good distinction between portions of the image which are in different colors. If the images seen are in monochrome, the original color of an object makes its contribution to the visual image only through varying shades of monochrome and portions of the images are distinguished by their relative densities.

Man's aural response is to compressional disturbances in an elastic medium—almost always air—covering the frequency range of from about 20 to about 20,000 cps. The sensitivity of the normal human ear is greatest to frequencies of about 1,000 to 2,000 cps, although the ability to perceive the full a-f range depends upon the age of the person and upon any hearing defects he may have.

Man's two ears, on opposite sides of the head, separated by a distance of about 6 or 7 in., hear sounds from a given source at slightly different times. When the two sounds are heard and combined in the brain, man is able to perceive depth or a third dimension through stereophonic hearing; he is able to determine reasonably well, therefore, the point in space from which the sound emanates.

53. Role of Sensory Perceptions in Communication. The type or character of the signal to be transmitted through a communication system depends upon the kind of intelligence to be conveyed. It also depends upon the sense which is to be stimulated at the receiver. Whatever sense is to be stimulated, appropriate energy-converting devices, transducers, are required at each end of the system. For example, in broadcasting, microphones are necessary to convert the acoustic energy to electrical energy at the transmitter and loud-speakers are required at the receiver to convert the transmitted electrical energy into acoustic energy.

The satisfactory design of energy-converting devices involves three factors:

1. Physical means for converting sensation-stimulating energy into electrical form and vice versa.
2. Means for determining the performance of the energy-converting devices in terms of physical energy as well as in terms of the sensations produced by energy converters. The criterion of distortionless transmission, already given, may often be employed to guide design. It may be technically impossible or economically unsound to construct distortionless system, but by having knowledge of the conditions for distortionless communication, the engineer can recognize the limitations beyond which practice cannot advance.
3. Knowledge of certain physiological characteristics of human beings, such as the relations between sensations or subjective responses and the physical stimuli producing such responses. It is particularly important to know, in as quantitative a manner as possible, the significant characteristics of speech, hearing, and vision, since such knowledge is of direct aid in the design of significant components of the communication system.

If the system is to be designed and built for use by normal persons, it is desirable to know, quantitatively, the normal human responses as determined from a statistically significant group of persons. The data obtained from a study of the subjective sensations and characteristics of a statistically adequate group may be used in the design of communication equipment for any type of service required by normal persons; but the obtaining of such information is not easy.

54. Evaluating Sense Perceptions. How is the communications engineer to determine the performance of the communication system in terms of measurements that are, in some way or another, related to sense perceptions? The desired objective is clear enough. What we would like to have is a set of instruments whose readings or indications of physical stimuli would correspond with the subjective evaluations of such stimuli when judged by a normal person occupying the same position as the instrument. In acoustics, for example, it would be useful to have an instrument to

measure sound pressure with readings proportional to the human subjective evaluation of the sound pressure.

There is a good deal of difficulty in providing such instruments, and only a beginning has been made. The real problem is that of determining the subjective estimates or evaluations of the physical phenomena evoking sensations. No direct measurements can be made; all correlations between the physical stimuli and estimates of the subjective effects produced must be done indirectly with groups of people making the necessary evaluations. Those selected for such tests must have normal responses, and this poses very real problems. A large number of persons must be employed and they must be properly conditioned. Finally, the kind of tests to be given, the conditions under which stimuli are produced and sensations evaluated, and the significance of the results obtained are all important problems in correlating the physical and the psychophysical phenomena.

Although, in making such psychophysical tests, each observer may obtain a different result, usually it will be found that, under identical conditions of measurement, observations by a large number of persons tend to cluster around a relatively small range of values, especially for persons whose responses are regarded as being "normal." Substantial deviations, on the part of a single observer or small number of observers, from the results obtained by a large number of persons are a very effective means for determining deviations from normal, especially if results from the "deviationists" tend to be inconsistent.

Data obtained from large numbers of persons by techniques such as these have sometimes been adopted as standard, after proper examination and evaluation of experimental technique and consistency of results. The standard audibility and visibility curves, for example, have been obtained in this way.

55. Hearing. The human ear is not responsive to pressure variations in a compressible medium over an infinite range of sound intensities. Some sounds are of such low energy level that they cannot be heard; other sounds may have such a high energy level that they produce pain or physical damage rather than the sensation of sound. The loudness of sounds is recognized as such only between the audibility threshold of hearing (the minimum level at which sounds can be heard) and the maximum or tolerance level of hearing (at which pain is produced).

The ear is, likewise, not equally sensitive to sounds of different frequencies. Sounds below about 15 to 30 cps are not perceived as sounds, whereas vibrations beyond about 15 or 20 kc are beyond the upper frequency range of audibility. At the extremes of hearing, the threshold of audibility merges with the threshold of pain.

For normal human ears, maximum sensitivity occurs for sounds from about 800 to 2,500 cps. Toward the ends of the a-f range, the ear is not as sensitive to low-intensity sounds as in the middle of the range. The thresholds of audibility and of pain tend to merge so that there is a smaller range of sound levels the normal ear recognizes at the frequency extremes than in the middle of the audible band.

Responses vary from person to person; they vary with the age of the individual and may even depend upon the audio environment prior to test, and persons having hearing defects have different responses than those with normal hearing.

The two ears are separated by a distance of about 6 or 7 in., and each receives a slightly different signal from the same sound source. Some estimate of the direction of a single sound source can be determined by turning the head so that each ear receives sound of equal intensity and with the same time delay.

56. Audibility Threshold. The threshold of hearing a specified sound is the minimum effective pressure of that sound which is capable of producing an auditory sensation in a noise-free environment in a specified fraction of all observations or tests. It is usually specified in decibels above a standard sound-pressure intensity of 0.0002 dyne per sq cm, which represents the threshold of hearing a pure 1,000-cps tone by persons having the most acute hearing.

The American Standard threshold of audibility is determined for a person with acute hearing listening to pure tones. Measurements are made in an anechoic

chamber with the observer facing the source of sound, which is at a distance greater than 1 m from him. The sound pressure is measured at a point where the observer's head will be located. Audibility-threshold curves determined in this way are shown as curve *A* of Fig. 9. Curve *B* of the same diagram represents the threshold of audibility when the sound is supplied by earphones and the sound pressure is determined at the entrance to the ear canal.

The two different methods of measuring audibility threshold disclose two significant differences. Curve *A*, for binaural hearing, shows that the threshold of audibility is about 10 db lower when two ears are involved than for one-ear, or monaural, hearing,
FIG. 9. Thresholds of audibility as determined by three different procedures. Curve *A* is for binaural hearing, with sound produced by single sound source in front of listener. Curve *B* is for binaural hearing with sound produced by number of randomly distributed sound sources. Curve *C* is for monaural hearing, with sound conveyed to listener by headset.

represented in curve *C*. The response for binaural hearing also has greater irregularities above about 800 cps. These are attributed to acoustical resonances in the outer ear canal, as well as to diffraction of sound around the observer's head.

A frequency of 20,000 cps is usually regarded as the upper frequency limit of audibility, but it varies with the sound level; it is different for different persons and is higher for young persons than for middle-aged or old people.

57. Tolerance Threshold. When sound is conveyed by earphones, listeners begin to experience discomfort when pure tones reach levels greater than 110 db and a tickling sensation when the tones reach levels of 130 db, reference level of 0 db being taken at a sound pressure of 0.0002 dyne per sq cm. Pain is experienced at sound levels of 140 db. Except at the extremes of the a-f range, these levels are not greatly dependent upon frequency. Persons customarily exposed to intense sounds have a higher tolerance threshold in each of the three categories than are indicated by the figures given above.

When the sound is noise instead of a pure tone, essentially the same sensations are aroused at the intensity levels given. It is not necessary, however, for all frequency components of wide-band spectrum noise to have the indicated level to produce the

stated sensation; when the energy in a portion of the spectrum reaches 110, 130, or 140 db, the sensations of discomfort, tickling, and pain, respectively, are usually encountered.

58. Loudness and Loudness Levels. In acoustics it is much more customary to measure the loudness level than to measure the loudness, which is the magnitude of the sensation. Loudness level is the intensity level of an equally loud reference tone, usually 1,000 cps. Loudness level is an experimentally determined quantity and is measured in decibels above a specified reference level. The reference level is 10^{-16} watt per sq cm, corresponding to sound pressure of 0.000204 dyne per sq cm and 0 db sound intensity.

For normal human ears, the average characteristics relating frequency and loudness level are shown in Fig. 10. The curves were obtained by alternately listening to a
Fig. 10. Contours of equal loudness for normal human ears. Numbers on the curves indicate the loudness levels.

sound of arbitrary frequency and intensity and comparing it with a tone of 1,000 cycles whose intensity was varied until the two sounds were judged to be equally loud. The curves of Fig. 10 show the relative insensitiveness of normal ears at low intensity levels for high and especially for low frequencies. The maximum range of intensity levels to which the ear responds is about 140 db, representing a power ratio of 10^{14} to 1 from tolerance level to threshold of audibility. The numbers on the different curves represent the estimated loudness levels in phons. The loudness level is a subjective evaluation in which any tone is compared with a tone of 1,000 cps and variable intensity. Since the comparisons are made at 1,000 cps, the loudness levels in phons and the intensity level in decibels are the same at a frequency of 1,000 cycles. At 30 cps a loudness level of 10 phons occurs when the intensity level is 70 db.

59. Minimum Perceptible Changes in Sound Pressure. A change in sound-pressure level of about 1 db can be detected for tones between 50 and 10,000 cps, provided the level of the tone is greater than 50 db above that tone's threshold value. If the sound-pressure level is less than 40 db above the threshold value, changes of from 1 to 3 db are required to be perceptible. Under unusually favorable conditions levels as small as 0.3 db can be detected by normal ears in the middle of the a-f range.
FIG. 11. Frequency and power ranges for the reproduction of speech and music.
FIG. 12. Thresholds of hearing for statistically large sample of American population. Numbers on the curves indicate the percentage of persons tested whose threshold of audibility was lower than that represented by the curve marked; *i.e.*, their hearing was more acute. Top curve represents threshold of feeling.

60. Minimum Perceptible Changes in Frequency. The ear can detect changes in frequency of about 0.3 of 1 per cent above 1,000 cps if the pressure levels are greater than 40 db above threshold value, or about 3 cps below 1,000 cps. For low levels of pressure, the minimum perceptible frequency change may be many times this set of values, especially at low frequencies.

61. Frequency and Power Ranges for Practical Aural Communication. From the contour curves for equal loudness for human ears, it may be determined that distortionless transmission of sounds by electrical means requires the transmission of frequencies of from 20 to 20,000 cps and the transmission of power ranges of as much as 10^{14} to 1. Few systems respond fully without distortion over this range, and none of them is capable of operating effectively over the full range of power ratios to which the ear is normally responsive.

Fortunately it is not necessary to reproduce the complete range of frequencies or loudness levels to obtain satisfactory, understandable, or enjoyable reproduction of speech and music. Estimates vary as to the frequency range and intensity levels that are desirable, particularly since economic factors must be taken into account, for extension of frequency range and intensity levels invariably is accompanied by increased cost. Furthermore, some types of audio service are more stringent in their demands than others.

FIG. 13. Hearing impairment as a function of age. Dashed curves represent data for women, solid curves for men. Numbers on the curves indicate the frequency at which observations were made.

The frequency and power ranges required for the satisfactory reproduction of speech and music are shown in Fig. 11. According to these data, little improvement in the reproduction of music is obtained by extending the frequency range below 40 cps or above 15 kc or by extending the intensity levels below 28 db or above 97 db. For persons of normal hearing, practically no gain justified by the increased cost will be achieved in transmitting speech at frequencies below 130 or above 5,000 cps, or by transmitting power levels outside those from 35 to 78 db. Indeed, intelligible speech can be reproduced with a frequency band of from 250 to 2,800 cps and for the reproduction of music, many broadcast receivers are so operated that their frequency band is limited to between about 100 and 3,000 cps. The highest-quality sound systems, on the other hand, are usually designed to reproduce frequencies from 20 to 20,000 cps.

Deviations from normal hearing occur in a significant fraction of the population and depend on age and sex as well as individual characteristics. They must be considered in economic communication systems. Figures 12 and 13 illustrate these deviations.

62. Sensation-Stimulus Relations. From the loudness-level curves of Fig. 10, it is possible to derive curves in which the loudness level is plotted against the sound pressure, as in Fig. 14. Such a relation shows directly the subjective evaluation of loudness level as a function of stimulus, within the framework of the experimental technique employed. If the Weber-Fechner law were rigorously true, the curves of Fig. 14 would be straight lines.

The psychophysical response of the human ear is not a linear function of the amplitude of the stimulus, if a sufficient range of the latter is taken into account. Measurements by Stevens and Newman show that, although the stimulus-sensation response
is linear for small values of sound-pressure intensity, amplitude distortion is produced within the ear itself for loud amplitudes of sound.

63. Frequency and Pitch. Frequency is a physical quantity measured with physical apparatus and specifies the number of oscillatory vibrations per unit of time.

Pitch, on the other hand, is an aspect of auditory sensation in terms of which sound may be ordered on a scale, such as a musical scale. The subjective quantity of pitch is primarily a function of the physical frequency of a sound, but not entirely so, for the pitch of pure tones is also dependent upon the sound intensity. The subjective determination of pitch is determined experimentally in terms of the physical property of frequency. An oscillator of known frequency and sound intensity is fed to a
FIG. 14. Relative loudness (psychophysical response) plotted against sound pressure (physical stimulus) for five different audio frequencies.

headset or loud-speaker. Another headset or loud-speaker is fed from another oscillator whose frequency is adjustable. For a range of frequencies of the first oscillator, the observer adjusts the frequency of the second oscillator until the pitch of the sound produced by both oscillators has some specified relationship. With such an experimental technique, a scale of pitch can be related to the frequency. Pitch is measured in units of the *mel*, and a reference pitch of 1,000 mels was chosen as the pitch of a pure tone of 1,000 cps having a sound-pressure level of 60 db.

The relation between subjective pitch, in mels, and frequency, in cps, throughout the entire a-f range of 20 to 20,000 cps is shown in Fig. 15. It is clear that pitch, as determined by the experimental technique outlined above, is by no means linearly related to the frequency of the sound.

64. Phase Shift. Conclusive evidence has not been obtained to indicate that the ear can evaluate phase shift in the components of a complex sound. The response of the ear to complex sounds appears to depend upon the magnitude of the harmonic content rather than upon the wave shape, which, for a specified amplitude-frequency spectrum, is determined by the phase shift of the harmonics compared with that of the fundamental wave. For this reason the phase-shift characteristics of a-f portions of communication systems can be, and frequently are, neglected.

Although the ear itself cannot distinguish the phase relations of the harmonics

of a complex sound, subsidiary (although usually minor) matters are observed as a result of phase shift. In a complex wave, the phase relations of the harmonics may influence the subjective sensations of a complex tone. Provided the fundamental frequency is less than 100 cps, a shift in phase of a harmonic may alter the subjective loudness of the harmonic; it may also produce a noticeable difference in the quality of the complex tone.

65. Masking Effects. A sound impressed upon the ear reduces the ability of the ear to hear other sounds and may even completely mask their presence. A sound is said to be masked by another when the intensity of the second sound is increased
FIG. 15. Tests of the evaluation of pitch indicate that a nonlinear relation exists between the observer's estimate of the pitch of a sound and its frequency. The two are taken to be equal at 1,000 cps.

to such a level that the first can no longer be heard. Masking is defined as the number of decibels by which the listener's threshold of audibility for hearing a given sound is increased by the presence of a second or masking sound. Suppose, for example, that, in the absence of noise or any other sound, the threshold of audibility for a given sound is 3 db. The presence of a second sound will make the first one inaudible until the level of the first has been raised to a higher level, say 36 db. Thus, the second tone produces a masking effect of 36 − 3, or 33 db.

When one pure tone is masked by another pure tone, the greatest amount of masking occurs when the two tones are nearly alike in frequency. For low-intensity levels of the masking tone, the masking effect is usually small when the frequency of the masking tone is double that of the original tone. As the intensity of the masking tone is increased, the masking effect of the interfering tone remains high so that all the tones of high frequency must be increased in intensity to fairly high levels before they can be heard. The effect of masking a pure tone by another pure tone is greater when the masking or interfering tone is above the tone being masked than when below it in frequency, when the two tones are heard simultaneously by one or both ears.

If the original and masking tones are introduced separately to each of the two ears the interfering effects are not the same as when introduced simultaneously into one

70. Speech Clipping. Limitation of the peak amplitude in speech is often employed in communication systems to improve the intelligibility of the received signal for a given amount of power generated and modulated at the transmitter.

The average power content in speech wave forms is appreciably less than that of a sine wave of the same amplitude value as the peak of the speech wave. The percentage of modulation is determined in terms of peak amplitudes, and for this reason, the power in the modulated wave or in the side bands of a transmitter modulated 100 per cent by speech wave forms will be much less than if the same transmitter were completely modulated by a sine wave.

If the magnitude of the speech wave form is now increased so that its average power is the same as that of the sine wave and if, furthermore, the amplified speech wave is clipped so that its maximum values do not exceed the amplitude of the sine wave, the speech will be able to modulate the transmitter 100 per cent. Of course the wave form of the clipped speech will differ from that of unclipped speech wave forms; the clipped speech will lose some of its naturalness, but the degradation for moderate amounts of clipping is not great so far as concerns articulation. Moreover, once the system is properly adjusted, the maximum amplitude of the speech is maintained at such a fixed value as to make overmodulation impossible.

In the process of clipping, certain undesirable high-frequency distortion components are generated, and these should be removed by filters, prior to modulation. Suitable filters should have relatively little attenuation for frequencies below 2,500 cps and high attenuation for frequencies above about 3,000 to 3,500 cps.

With 6 to 12 db of clipping the change in quality of speech is small, but four to sixteen times as much speech power can be transmitted as without clipping. Clipping of as much as 25 db can be employed without too much loss of intelligibility.

71. Vision and the Communication System. The introduction of picture and television communication systems has made it imperative that the communication engineer have some acquaintance with the properties of light as well as the visual characteristics of the human eye, for the requirements of satisfactory visual communication systems are much more stringent than those to be fulfilled for a satisfactory aural system. Only the most elementary matters of vision and visual responses can be mentioned here; for more details reference should be made to specialized works on optics, vision, psychology, or "human engineering."

72. Light and Vision. In a physical sense the term "light" refers to electromagnetic radiation of such wavelength as will produce a visual sensation in the normal human eye. The term light is sometimes also used to refer to wavelengths shorter than or longer than those of the visible spectrum. Vision, on the other hand, depends upon the ability of the eye to transform light stimulus into impulses that are transmitted to the brain through nerve fibers. The undistorted perception of contrast and color, of shade, depth, motion, direction, and most voluntary thought processes depend upon the response of the eye to light. Thus, vision is a subjective response to a physical stimulus.

Frequently the term "light" is used to describe either the radiant energy capable of producing a visual sensation, or the sensation that is produced by radiant energy. Physicists usually use the term in its physical or objective sense. On the other hand, physiologists and psychologists usually use the term in its subjective sense.

From the physical point of view, light is a form of electromagnetic radiation similar to radio waves except for their wavelength or frequency. Thus, except for those factors depending upon wavelength or frequency, the comments given here on light apply equally well to radio waves.

In free space light travels with a velocity of 2.99796×10^{10} centimeters per second (186,000 miles per second). Light is a transverse wave motion consisting of electric and magnetic vectors at right angles to each other and to the direction of propagation. It may be polarized, reflected, absorbed, refracted, absorbed, or transmitted in various degrees by materials upon which it falls.

Table 3. Approximate Wavelength and Frequency Limits of Colors in the Visible Spectrum

Spectrum color	Frequency limits, cps	Wavelength limits, mμ
Infrared	Less than 4.0×10^{14}	Greater than 750
Red	$4.0\text{–}4.8 \times 10^{14}$	750–630
Orange	$4.8\text{–}5.0 \times 10^{14}$	630–600
Yellow	$5.0\text{–}5.2 \times 10^{14}$	600–580
Green	$5.2\text{–}5.9 \times 10^{14}$	580–510
Blue	$5.9\text{–}6.5 \times 10^{14}$	510–460
Violet	$6.5\text{–}7.5 \times 10^{14}$	460–400
Ultraviolet	Greater than 7.5×10^{14}	Less than 400

Selective reflection (or transmission) and absorption account for the colored appearances of objects seen by the eye. Thus, an object which absorbs to a high degree a portion of the visual spectrum will present to the eye the color sensation corresponding to white light minus the portion absorbed. That is, the only portion affecting the eye is the portion reflected (or transmitted) to the eye.

The human eye is a highly specialized organ, remarkably (but not uniformly) sensitive to electromagnetic energy between the approximate limits of 400 and 750 millimicrons. Light, impinging upon the eye and focused by the lens, produces an image on the retina whose form, change of position, intensity, and spectral energy

istribution are subjectively interpreted in terms of shape, motion, brightness, color, ..d other attributes of objects in the physical world.

The eye can distinguish details of the image and differentiate distant objects from nearby ones, in part, by the relative sharpness of detail of their images. The relative distances and positions are inferred from the angles between the lines of sight from the eyes to the objects in question, and by the relative angles subtended by objects of known size. The eye receives sensations of color from light of different wavelengths but is not able to analyze a given color sensation into its spectral components.

The eye has the ability to admit more or less light to the retina by varying the pupillary aperture, and thereby can adapt human vision to a wide range of ambient light intensity or brightness.

From a point of fixation straight ahead, the field of vision of the human eye extends more than 90° outward, 70° downward, 60° inward, and 50° upward. The two eyes see slightly different visual images because of their interpupillary separation. The slightly different views seen by the different eyes give rise to stereoscopy, by which the relative size and distance of objects are also determined.

73. Standard Visibility Function. The human eye is not equally sensitive to all wavelengths it is able to detect. For normal levels of illumination, the eye responds to all wavelengths between about 400 and 750 millimicrons; it is least sensitive to wavelengths at the extremes of this band and most sensitive to an intermediate or mean value in the yellow-green portion of the spectrum. Different eyes (even in the same individual) may have different spectral sensitivity or visibility functions.

FIG. 17. Visual sensitivity of the normal human eye for ordinary day vision and for vision at very low levels of intensity.

If the energy of the visual spectrum is passed through a prism and narrow slit so that monochromatic radiation of any selected value can be impressed on the eye and if the intensity of the radiation can be varied at will, it will be found that maximum spectral sensitivity occurs at 554 millimicrons for the "normal human observer." The relative sensitivity of the normal human eye to monochromatic radiation of other wavelengths (for light of normal intensity) is shown in Fig. 17. If the intensity of the light is substantially reduced, the spectral sensitivity curve shifts to shorter wavelengths, becoming maximum at 515 millimicrons. The spectral sensitivity, or standard visibility, curve shows the relative brightness of radiant energy for equal energy at each wavelength in the visible spectrum.

74. Contrast Sensitivity. If an object is to stand out from a background having the same color, contrast in brightness must exist between the two when both are illuminated by the same radiation. The minimum detectable difference in brightness between two large, contiguous surfaces is used as a test for contrast and contrast sensitivity. The surfaces used should subtend an angle of several degrees at the eye, and the light intensity of the two fields is adjusted until the observer notes a just perceptible difference between the two. The ratio of the difference in brightness of the two fields to the mean brightness is called the *contrast*. *Contrast sensitivity* is the reciprocal of the contrast as defined above.

Contrast and contrast sensitivity depend upon the surround of the illuminated areas. If the surround is illuminated, much greater values of contrast sensitivity can be determined than if the surround is dark. If the surround is illuminated, contrast sensitivity increases linearly with the logarithm of the background illumination,
whereas, if the surround is dark, saturation effects occur and a small range of contrast is observed, as shown in Fig. 18.

75. Resolving Power. When there is an appreciable amount of contrast between an object and its background, the eye has the ability of distinguishing between objects having small angular separation, and can also distinguish fine detail.

The degree to which the eye is able to distinguish objects separated by a small angle is called resolving power and depends upon the kind and shape of the object, the degree of contrast between it and its surround, the spectral distribution of the energy of illumination, the criterion used to determine or evaluate perception of the object, and other factors. Depending upon the experimental conditions of the test, this property lies in the range of about 0.1 to 1 minute of visual angle; that is, under the most favorable circumstances, objects can be seen separately if, at the observer's eye, they subtend an angle of 0.1 to 1 minute of arc.
FIG. 18. Contrast sensitivity of the human eye at various levels of background luminosity for illuminated and dark surrounds.
FIG. 19. Visual acuity as a function of the luminosity of the background for normal human eyes.

76. Visual Acuity. Whereas resolving power is related to the minimum detectable visual angle, visual acuity is the ability of the eye to distinguish fine detail. Sometimes visual acuity is expressed as the reciprocal of the angle, in minutes, which the smallest detail in a test object subtends at the eye; thus visual acuity becomes equivalent to the reciprocal of the resolving power. Acuity may also be expressed as either (1) the ratio of the distance at which a given line of letters on a test chart can be seen by the observer being tested, to the distance which an observer with normal vision would see it, or (2) a visual rating (expressed in per cent) related to the size of characters in lines of letters of different size. The first method is employed with the Snellen test chart; the second with the test chart of the American Medical Association. As shown in Fig. 19, visual acuity increases with the amount of illumination, or the brightness of the image.

77. Flicker and Persistence of Vision. A visual image may be fully perceived by a viewer in about 0.01 sec after it has been projected onto a screen. The visual impression does not immediately vanish upon being removed from the screen suddenly, but persists as an afterimage for about 0.05 sec. This phenomenon, called the per-

sistence of vision, is employed in motion pictures and in television to create the illusion of motion by exhibiting, in rapid succession, a series of images that are similar to one another but individually different in those portions of the frame in which motion occurs. The effects of persistence of vision depend upon the luminosity of the subject, and below a certain interruption rate (which depends upon luminosity) the persistence of vision vanishes and flicker is observed. Flicker is usually annoying and objectionable.

If 20 or more frames or images are viewed per second from a sequence of frames which are alike except where motion has occurred between the making of one frame and the next, and if the successive images from each frame can be reconstructed before the visual impression of the preceding one has been lost, the sensation produced is one of apparent continuous motion, and the images are reasonably free from flicker. As shown in Fig. 20, the frequency of flicker is not constant but depends upon the field luminosity.

78. Color Vision. The eye is incapable of analyzing a complex stimulus into its spectral components; in this respect there is a fundamental difference between the eye and the ear. Because the eye cannot analyze radiation into its spectral components, an infinite number of stimuli will, in general, evoke a given hue sensation.

It is found that a color stimulus can be matched visually by proper combination of three color attributes. Thus, three numbers (which may be chosen in different ways) are generally necessary, and are always sufficient, to specify the sensation-evoking characteristics of a given radiation.

FIG. 20. Critical flicker frequency for human eyes.

A color match may be produced by means of a pure spectral color to which varying amounts of neutral (gray) light have been added. In this method, color may be specified in terms of the physical quantities of (1) dominant wavelength, (2) purity, and (3) luminosity, which correspond roughly to the subjective sensations of (1) hue, (2) saturation, and (3) brightness, respectively.

A color match may also be produced by mixing three stimuli, called *primaries*. To produce a match of the proper brightness, the intensity of the three primaries may need to be varied as well as their relative amounts, which determine the hue of the mixture. The primaries for achieving visual color matches are usually taken to be red, green, and blue, but they may be other hues—or even monochromatic radiation—and may be arbitrarily chosen so long as some amounts of all three components are needed to produce a subjective color match. Color specification in terms of amounts of the three primaries required to produce a match does not correspond to any commonly accepted sensation attributes.

The spectral energy curves of three primaries established by international agreement in 1931 are shown in Fig. 21. The primaries are selected so that equal amounts of all three are required to produce white light. A convenient simplification has been achieved by selecting one of the primaries to coincide with the visibility function of the normal human observer.

79. Hue, Saturation, and Brightness. Every color sensation has three qualities which we may call (1) hue, (2) degree of saturation, and (3) brightness. These qualities are related to the physical attributes of (1) dominant wavelength, (2) purity, and (3) luminosity, and form the basis of color television systems of matching color sensations.

Hue is that attribute of color by virtue of which it differs characteristically from gray of the same brightness, and in respect to which it falls into classes we may
designate as red, orange, yellow, green, blue, or violet, or intermediates of these. Hue may be expressed as a spectral wavelength; in physical measurements it is designated as the dominant wavelength.

The degree of *saturation* of a color refers to the absence of neutral or gray light. Pure spectral colors without admixture of gray (white) light are said to be saturated; they are less saturated in proportion to the amount of white light added to effect a color match. Saturation is a term that describes the absence of white light mixed with the hue. Pale or pastel shades of hue are less saturated than the vivid shades; pink is white with some red and is but slightly saturated.

The *brightness* of a color depends upon the intensity of the energy reaching the eye. Brightness is a characteristic by means of which colors are located on a scale ranging from light (white) to dark (black). Saturation and brightness are somewhat related, for saturation refers to the degree by which a color departs from gray or neutral hue of the same brightness.
FIG. 21. Distribution coefficients for C.E.I. primaries selected for colorimetric work. The curve marked y is the same as the visual sensitivity of the eye for high light intensities.
FIG. 22. Chromaticity diagram or color triangle. The horseshoe-shaped curve shows the locus of all spectrum colors, the wavelength in millimicrons of the spectral colors being designated by the numbers on the curves. White light is represented at the center of the diagram (x = 0.31; y = 0.31).

Hue and saturation, together, are sometimes called *chroma*. Thus, the chromaticity characteristics tell everything about the color except its intensity or brightness.

To completely specify a color sensation, it is necessary to give the hue (the wavelength of the dominant hue), the quantity of white light mixed with it (or the degree of saturation), and the intensity of the color (as determined by its brightness or brilliance). Two colors are said to be visually alike when they are in agreement in all of these three respects.

80. Representation of Colors. A basic tool in the study and specification of color is the *chromaticity diagram*. Chromaticity is that characteristic of color representing hue and saturation together; it describes two of the three properties of color, omitting brightness.

The most commonly used chromaticity diagram is the kind of *color triangle* shown in Fig. 22 and based on the color mixture curves or primaries of Fig. 21. The color mixture curves show the amounts of the three primaries, X, Y, and Z, that are required to match unit energy at each wavelength in the visible spectrum. The diagram of Fig. 22 may be regarded as a standardized color map for the system of colorimetry used by the International Commission of Illumination. The primaries used in the National Television Systems Committee signal specifications are given in this system of color measurement and appear as points in the diagram of Fig. 22.

81. Colorimetric Basis of Picture Transmission. Because any color may be matched by proper amounts of three primary colors, any color image may be resolved into three partial images each of which represents the contribution of one primary-color component to the total colored image. Thus the red, green, and blue partial images represent, respectively, the amount and spatial distribution of the red, green, and blue hues of the original colored images; except that the partial images analyze the original view on a color basis, they have the same size and amount of detail as the original colored image. Each partial color image may be considered to be a monochrome visual image, on a color basis, of the original.

Each of the three partial images may now be analyzed into picture elements by a suitable scanning process, converted into magnitude-time functions of electrical phenomena, and synthesized at the receiving end into another partial image. So far as each partial image is concerned, the process is the same as the electrical transmission of a monochrome picture. Now, however, three partial images must be transmitted—one for each primary color—and each partial image reconstructed at the receiving end of the system must control or produce light of the appropriate primary stimulus. When this is done and the three reconstructed partial images are superimposed, in register, the original color image may be reconstructed.

If a single still view is to be transmitted in color, the time of transmission is usually not of major importance, and a fairly narrow band width can be used to transmit colored images by electrical means. On the other hand, if colored pictures are to portray motion, each set of three partial images for any given frame of the colored image must be scanned, its electrical wave form must be transmitted, and the new image must be reconstructed in something like 0.01 sec if the effects of flicker are to be minimized.

It is possible to transmit all of one partial image at one time, and to follow this by the transmission of all of the remaining partial images. But it is also possible to transmit one element or one line of the red-color image, followed by one element or line of the green-color image, and then one element or line of the blue-color image, in repetitive fashion. Details of the various systems in current use are covered in other chapters of this handbook.

ELECTROMAGNETISM AND THE STRUCTURE OF MATTER

82. Properties of Materials. Communication engineering is concerned with analytical methods of expressing and representing intelligence, particularly in terms of the human responses of the senses—especially hearing and seeing. The basic concepts of this phase of communication have already been outlined for any type of communication system. Electrical-communication systems are concerned with the utilization of electromagnetism as the vehicle by which information, originating at one part of the system, may be conveyed to another portion of the system. In radio-communication systems, conveyance of information through the use of electromagnetic radiation is a primary concern. Electrical-communication engineering thus rests squarely upon the fundamentals of electromagnetism, which is the subject of the remainder of this chapter.

Engineering applications of electricity involve the use of material bodies, not only to give form, embodiment, and mechanical strength to the necessary structures, but also to make possible the creation of electric and magnetic fields of the desired

magnitude and spatial distribution, together with the desired and effective utilization and storage of electromagnetic energy.

In the design of communication apparatus, the physical, thermal, optical, acoustical, chemical, and especially the electromagnetic properties of materials play important roles in making possible the desired performances. A vast amount of investigation has shown that the properties of materials depend, in large measure, upon their structure in terms of the elementary particles of nature, and upon the processing to which they are subject. It is not yet possible to predict or predetermine the properties of materials in terms of their composition and structure, but considerable progress is being made in this field, which has been referred to as molecular engineering.

The subject of the properties of materials, as determined by their structure in terms of molecules, atoms, and the more elementary particles of nature, is such a vast and extensive one that specialized treatises should be consulted for further information. Only the barest outline of a few factors upon which the electromagnetic properties of materials depend can be given here. Already significant progress has been made in relating the conductive, dielectric, and magnetic properties of materials with their composition and structure, and the time may come when it may be possible to specify the electromagnetic properties of materials and have suitable substances made to order with the desired characteristics. Indeed, the rapid progress that has been made in semiconductor devices is, in large measure, attributable to a thorough understanding of the relation between the properties of materials and their composition and structure.

83. Structure of Matter. Many experimental observations, particularly within the last half century, have conclusively demonstrated the atomic nature of electrical and magnetic phenomena, and the close dependence of electromagnetic effects upon the ultimate structure of matter.

So far as the engineer is concerned, most if not all of the phenomena with which he deals can be explained by the simple atom model composed of a compact stable central core or nucleus made up of relatively dense particles called *neutrons* and *protons*. Around the core electrons revolve in elliptical shells or orbits at distances large compared with the size of the nucleus. The electrons spin on their own axes.

At least 27 fundamental particles were recognized by the end of 1957, but most of these have very short lives (small fractions of a second) and do not enter into electromagnetic phenomena ordinarily encountered by the communications engineer. The stable particles of physics are shown in Table 4.

The electromagnetic properties of matter are largely associated with these electrons, and the communications engineer need not concern himself too much with the central core or nucleus.

The modern view of electricity regards an electric current (at least the conduction and convection components of the total current) as the flow of negative charges in one direction through a given area, plus the flow of positive charges (when these are free to move) through the same area in the opposite direction. In most cases the negative charges accounting for current are due to the motion of electrons, whose properties are given in Table 5. By common agreement, the positive sense of the direction of current is taken as that in which positive charges tend to move or (what is the same thing) opposite that to which negative charges move or tend to move. This convention was adopted before the true nature of the electric current was known, and since (in most cases) the electric current is constituted by the flow of electrons, the anomalous and awkward situation arises that the direction of flow of electricity is frequently in a direction opposite to the flow of charged particles that produce the current! For engineering-design problems, it makes little difference what the true direction is, but when this is important, as in the case of rectifiers, for example, care should be taken to specify whether the direction of flow is that of the electrons or of positive charges.

The motion of electric charges is produced by the application of electrical forces to material substances. The application of such an electrical force tends to dissoci-

ate particles of the substance into charged particles whose motion is produced by the electrical force and constitutes a current. The charged particles may be electrons, removed from atoms, or electrically charged atoms, called *ions*. A substance such as any of the metals, carbon, alkaline or saline solutions, or ionized gases, in which relatively large drift of electrons or other charged particles is produced by relatively small externally applied electrical force, or in which the charges may travel freely in distributing themselves within the substance, is called a *conductor*.

Table 4. Properties of Elementary Particles

Name	Symbol	Relative mass	Relative charge	Spin	Principal characteristics
Photon	γ	0	0	1	A quantum of electromagnetic energy, of magnitude $h\nu$, where h is Planck's constant, and ν is the frequency associated with the photon
Neutrino	ν	0	0	½	Existence postulated to account for continuous energy distribution of β particle, and required to conserve angular momentum in β decay processes; has negligible reaction with matter
Antineutrino	$\bar{\nu}$	0	0	½	Emission is hypothesized to accompany radioactive decay by positive emission or electron capture, or to conserve energy when proton changes to a neutron
Electron	e^-	1	−1	½	Fundamental stable particle, making up structure of atoms; arrangement of electrons in atomic orbits accounts for chemical and electrical properties of atoms
Positron	e^+	1	+1	½	Positive electron, formed in β decay of many radio nuclides, in pair production, and in other processes; secondary constituent of cosmic rays
Proton	p	1,835	+1	½	Equivalent to nucleus of hydrogen atom, and constituent of all atomic nuclei; accounts for charge of nuclei and about half of nuclear mass
Neutron	n	1,837	0	½	Neutral-charge, electron-proton combination; constituent of all nuclei having mass greater than 1; half-life, about 12 minutes

Table 5. Properties of the Electron

Rest mass of electron, m_0	9.1066×10^{-31} kg
Charge of electron, e	1.60203×10^{-19} coulomb
	1.60203×10^{-20} abcoulomb
	4.8025×10^{-10} statcoulomb
Ratio of charge to mass (e/m_0)	1.7592×10^{11} coulombs/kg
Size of electron (roughly)	1.9×10^{-15} m

A substance such as sulfur, glass, porcelain, mica, rubber, quartz, very pure water, many oils, and un-ionized gases, in which measurable amounts of current may be produced (without disrupting the material itself) only by the application of comparatively large electrical force, or in which charges are bound within certain small regions and are not free to distribute themselves readily within the substance, is called a *dielectric* or *insulator*.

There is no sharp dividing line between conductors and insulators. The classification of a material into conductors or insulators depends in part on its application. A substance that might be regarded as a good insulator for some applications might also be regarded as a fairly good conductor for other applications.

Substances intermediate between good conductors and good dielectrics are sometimes also called *semiconductors*, although within the past decade this term has come to designate a certain class of materials having rather specific properties in addition to poor conductivity.

Conductivity depends upon the ease with which charged particles, free to move, may be produced under the influence of an electrical force, and this in turn depends upon the atomic structure. Dielectric behavior, on the other hand, depends upon the degree to which charged particles are tightly bound within the atoms and molecules of the material, and again, these properties depend upon atomic and molecular structure.

Finally, the magnetic properties of a substance—and particularly its ferromagnetic properties—depend not alone upon the structure of individual atoms but also upon the manner in which atoms are grouped into regions, called *domains*, and the behavior of the various domains in the entire substance. Thus the crystalline structure of the ferromagnetic material is of considerable importance.

84. Electrical Conduction. Electrical conduction depends upon the availability of charged particles that are free to move through the circuit. The number and kind of charged particles depend upon the state of the conductor, *i.e.*, whether it is a solid, a liquid, or a gas.

In the conduction of electricity through gases, the normal gas atom is ionized by the electric field to which it is subjected. In this process one or more electrons are stripped from the outer shells or orbits. Under the influence of the electric field, the electrons are accelerated in one direction, and the remaining part of the atom—a positive ion—is accelerated in the opposite direction, but with considerably less mobility because of its greater mass.

In the conduction of electricity through liquids—electrolytic conduction—the charged particles are the positive and negative ions formed by electrolytic dissociation. If the liquid is monatomic, the positive ions are merely atoms of the liquid from which one or more electrons have been removed, whereas negative ions are atoms having an excess of their normal complement of electrons. If the molecules are composed of more than one kind of atom, they may dissociate into their atomic form but with electric charge, so that each dissociated particle contains electric charge but has mass essentially that of the atom rather than that of the electron. Both kinds of ions are active elements of conduction current. Unlike the situation in gaseous conduction, however, in electrolytic conduction the positive and negative ions have much more nearly the same mass and mobility, and therefore the total current is more evenly divided between the two kinds of ions of opposite charge.

In the conduction of electricity through a vacuum or by metallic conduction the positively charged particles are not free to move, and for such cases, the electric current is due entirely to the flow of electrons.

The flow of electricity through metals is due to the motion of free electrons within the metal. The crystals of solids are pictured as a three-dimensional lattice of atoms. The atoms are regarded as being essentially fixed in their positions, although they can vibrate about their positions of equilibrium. Metallic conductors for electrical use are formed from crystals in which the lattice structures are almost identical.

The metals are usually fairly dense and have a complicated atomic structure. The outer-shell electrons—the valence electrons—move within a complicated electric field composed of the positive field due to the protons in the nucleus, and the negative field of the extranuclear electrons. The outer-shell electrons are less firmly attached to the atom, not only because they are further from the field of the protons but also because the positive proton field is more or less neutralized by the negative field of the inner-orbit electrons.

The valence electrons are loosely connected to their respective atoms, and can be removed rather easily by an electric field and can thus be made free to travel between the atoms of the lattice. The good conducting properties of the metals are attributed to the fact that there are something like 10^{22} free electrons per cubic centimeter in metallic crystals.

At very low temperatures, the free electrons of metals are able to move readily under the influence of an electric field. At higher temperatures, the thermal agitation of the atoms of the metals introduces a certain impediment to free motion which is

manifest by an increase in electrical resistance. Metallic conduction is dependent upon the temperature as well as upon the crystal structure of the solid; it may also be appreciably influenced by the presence or absence of impurities which affect the homogeneity of the structure of the crystals of the conducting solid. The effect of impurities is much less in good conductors than in semiconductors, however.

85. Semiconduction. The term semiconductor has been used to designate a class of materials having conductivities intermediate between those of good conductors and good dielectrics. Semiconductors have negative coefficients of resistivity, their electrical properties are sensitive to impurities and methods of preparation, and the type and degree of atomic binding force differ from those of good conductors.

The high conductivity of metals commonly used in electrical engineering is the result of very weak bonds between the valence electrons and the atomic nuclei. In semiconductors, however, the valence electrons are an integral part of the structure of the substance; accordingly they are relatively fixed and fairly tightly bonded in their positions in the atom. For semiconductors made of ideal crystals in which the electrons are firmly bound within the crystal structure, no conduction would be possible and the material would behave as a dielectric. Some slight impurities always exist, or the crystal structure may not be perfectly symmetrical; in such cases a slight excess or deficiency of electrons may be available for conduction. The number of available electrons or the number of *holes* (absence or deficiency of electrons) is so small, compared with the number of atoms, that poor conductivity results.

When a few excess electrons are available, they can travel through the lattice structure of the crystal under the influence of an electric field, and this constitutes a conduction current. If the material has a dearth of electrons, it is said to possess "holes." A *hole*, therefore, may be considered as the absence of an electron, or it may be considered as equivalent to a positive charge. If a material containing holes is subjected to an electric field, electrons from adjacent atoms will progressively move to fill the hole. As the electrons move in one direction to fill the hole, the hole may be regarded as traveling in the opposite direction. Thus the hole can account for conduction just as an electron can, although the hole moves in a direction opposite to that of the electron.

Electrons and holes can be introduced into the lattice structures of metals by impurities, but a few electrons and holes can occur in the semiconducting metal itself. Semiconductors are found in the middle of the periodic table, where the valence of the material is 4. Materials of valence 3 or 5, when introduced as impurities in small amounts, increase conduction by injecting holes or electrons. When the crystal structure is exceedingly pure, the behavior of the semiconductor is almost like that of a dielectric or insulator. On the other hand, impurities to the extent of but 0.001 per cent are sufficient to make the material behave as a good conductor.

86. Dielectric Behavior. Dielectrics have no appreciable electrical conductivity. As a consequence of their nonconducting properties, they must be able to support electric strain when subject to the influence of an electric field. They should also return to the system the energy they absorbed when strain was created within the dielectric by an electric field. Materials composed of atoms from the central part of the periodic table tend to produce good dielectrics.

These atoms are neither strongly electropositive nor strongly electronegative; they usually form chemical bonds, in compound formation, by sharing outer-shell or valence electrons to complete their outer octet of electrons. Materials having such bonds—called *covalent bonds*—contain electrically balanced molecules in which ions are not produced, and therefore electrical conduction does not occur.

Good dielectrics are frequently composed of molecules made up of slightly electropositive and slightly electronegative atoms held together through covalent bonding. Although the molecules as a whole do not have electric charge, the component ions of the atoms themselves do, and these are subject to electrical forces. In other words, the molecules of the dielectric may be thought of as being composed of molecules

which are dipoles, fixed in position. In an electric field, the ions constituting the dielectric tend to become slightly displaced from their normal position.

If a dielectric composed of dipole molecules having random orientation is subjected to an electric field, there will be a transient or temporary rotation of the molecule dipoles so that they may align themselves with the direction of the applied field. The molecular rotation of the ions in the direction of the electric field lasts for a very short interval of time but produces a displacement current within the dielectric in the process. When the electric field is removed, the molecules are able to resume their random orientation; in so doing they produce a transient or temporary displacement current within the dielectric in a direction opposite to that which occurred when the electric field was first applied; they thus give up the energy imparted to them when the field was first applied.

87. Magnetic Behavior. Although it is possible to distinguish between at least five different kinds of magnetic materials—according to their atomic or molecular structure—ferromagnetic materials constitute the materials of greatest engineering importance; only ferromagnetic materials will be dealt with here.

In the crystal lattice of ferromagnetic materials an electron is shared by several ions. As a result, strong forces of interaction exist, and these tend to align the spins of electrons of all ions in a certain microscopic crystal domain.

Ferromagnetic materials are viewed as consisting of many small regions, called *domains*, which may be larger or smaller than a crystal grain. Within each separate domain, the atoms are presumed to be aligned in a given direction as a result of the interaction forces mentioned. In the unmagnetized state, the atoms of the different domains are randomly oriented and no net or resultant magnetic effect is observed. When a magnetic field is applied to such a ferromagnetic material, however, the magnetization increases. For small magnetizing forces, those domains in which the atoms are nearly aligned with the direction of the magnetic field are oriented in its direction. As the magnetizing force increases, other domains are aligned with it, but at a decreasing rate, until finally saturation is reached when all domains are aligned in the direction of the applied field.

ELECTROSTATICS

88. Definition. Electrostatics is that branch of science which deals with the laws of electricity at rest. Historically, it is the oldest branch of electricity, but it has little direct application to electrical communication, which requires that some electrical quantity vary with time if intelligence is to be transmitted. The ideas originally developed in the study of electrostatics are but special cases of more general relations of electromagnetism.

89. Electric Charges. For all engineering purposes, electrified particles are completely specified by the magnitude and sign of their electric charge and by their rest mass.

An electron is the natural elementary quantity of negative electricity or the natural elementary negative electric charge. The charge (or quantity of electricity) of an electron, represented by the symbol e, is -1.602×10^{-19} coulomb, and the rest mass of an electron is 9.107×10^{-31} kg. Alternatively, one may define the coulomb, the unit of charge for engineering purposes, as the charge whose magnitude is equal to that of 6.242×10^{18} electrons, and the kilogram as the mass represented by 1.098×10^{30} electron rest masses.

A proton is the natural elementary quantity of positive electricity or the natural elementary positive electric charge. The charge of a proton is numerically equal to the charge of an electron but is of opposite sign, or $+1.602 \times 10^{-19}$ coulomb. The rest mass of the proton is 1,835 times that of the electron, or 1.671×10^{-27} kg.

The quantity of electricity, electric charge, on (or in) a body is the excess of one kind of charge over that of the other. A plus sign indicates an excess of protons or positive ions or, conversely, a deficiency of electrons or other negative charges. Likewise, a minus sign indicates an excess of negative charges or a deficiency of positive charges.

90. Electric Field. Associated with each electric charge is a sphere of influence or a field of force, which tends to accelerate or impart motion to other charges in the field
FIG. 23. Representation in a two-dimensional plane of lines of force about isolated electric charges.

of force. Such a field of force is detected only by the force it exerts on charged particles. The charge and its own field of force cannot be separated; indeed, the charge is sometimes looked upon as the point at which the field may be considered to be concentrated.

Since any charge is the result of the excess or deficiency of electrons, the charge, Q, of any substance is given by $Q = \pm ne$, where n is any integer expressing the number of elementary charges involved and e is the numerical value of the electronic charge. The sign of the charge, Q, is positive (+) or negative (−) depending upon whether the charge produces a force on other charges like that of a proton or an electron, respectively.

The sphere of influence, or the field of force, surrounding a charged particle is represented by lines of force that originate at the center of the charge and radiate outward in straight lines in all directions, as shown in Fig. 23. The direction of the lines of force designate the direction of the force that the charge exerts on an arbitrarily selected positive test charge, and the density of the lines of force is proportional to the magnitude of the force.

Since electrical effects in free space are propagated with the velocity of light, the field of any element of charge may be supposed to be emitted continuously from that element and to spread out in all directions from it with the speed of light. Such a view should not be regarded as a "true explanation" of actual physical behavior, of

course, but rather as a convenient means of accounting for the fact that electrical effects, due to the motion of charges, at a distance from the charges are observed to take place after a time interval whose magnitude depends upon the distance between the charges and the points of observation. Electrical effects at a distance are retarded in time.

91. Lines of Force and Tubes of Force. The properties of charged particles may be represented by means of lines of force, a concept to which Faraday attached physical significance. A line of force may be considered as a path indicating the direction of the force applied upon a positive test body (charge) in an electric field. A line of force in an electric field is a curve so drawn that, everywhere, it indicates the direction of the electric intensity, the sense in which the line is described being indicated by an arrowhead on the diagram to show the direction in which the positive test charge would tend to move if placed at the position of the arrowhead.

FIG. 24. Tube of force between two charged bodies.

A bundle of a large, but constant, number of lines of force is known as a "tube" of force. For a single isolated charge, the tube of force is actually a cone, but in most cases it is truly represented as a tube, as shown in Fig. 24.

92. Charge Density. A point charge, *i.e.*, an electrical charge so small that it may be considered as concentrated at a point in space, is the basis of electrostatics, and it

FIG. 25. Surface and volume charge density for electric charges distributed over a surface (left) or throughout a volume (right). The surface and volume are infinitesimal in size.

is conceivable that electrical problems could be solved in terms of point charges only. When many charges are to be dealt with, however, such a procedure becomes tremendously tedious and cumbersome and, in such cases, the concept of charge density is particularly useful in simplifying the solution of electrical problems. Two kinds of charge density of practical importance may be distinguished.

If the point charges are distributed over a surface area, as shown in Fig. 25*a*, the surface charge density, σ, is defined as the limiting ratio of the charge to the surface area, as the area approaches zero. If, in mks units,[1] Q is the charge in coulombs and

[1] In this section, electrical quantities are expressed in meter-kilogram-second (mks) units since this system was recommended for adoption after January, 1940, by the International Electrotechnical Commission. Conversion from the mks to the cgs units may be made by means of the conversion

s is the surface area in square meters, the surface charge density in coulombs per square meter is defined to be

$$\sigma = \lim_{\Delta s \to 0} \frac{\Delta Q}{\Delta s}$$

If the charges are distributed throughout a volume, V, as shown in Fig. 25b, the volume charge density, ρ, is defined as the limiting ratio of the charge to the volume, as the volume approaches zero. If Q is the charge in coulombs and V is the volume in cubic meters, the volume charge density is defined mathematically as

$$\rho = \lim_{\Delta V \to 0} \frac{\Delta Q}{\Delta V}$$

The charge density is defined at a point on a surface or in a volume, and its magnitude may vary from point to point. The sign of the charge density is that of the charge.

93. Electric Field Intensity. The electric field intensity (also called "electric intensity," "electric field strength," or "electric force") at a point is a vector whose direction is that of the force that would be exerted on a charged particle placed at the point and whose magnitude is equal to the ratio of the force to the charge of the electrified (charged) particle, provided the latter is sufficiently small so that it does not measurably affect or alter the electric field. A vanishingly small charge must, therefore, be employed as the test body to measure the electric field intensity. Hence, the electric field intensity may be defined mathematically as

$$\mathcal{E} = \lim_{\Delta Q \to 0} \frac{\Delta f}{\Delta Q}$$

where, in mks units, f is the force in newtons, Q is the charge in coulombs, and $\mathcal{E}$ is the electric field intensity in volts per meter.

94. Coulomb's Law. As early as 1773, Sir Charles Cavendish made the first quantitative measurements in the field of electricity and deduced the relation between the forces exerted by charges, but his results were unpublished and remained unknown for almost a century. In the meantime, in 1785, Charles Augustin Coulomb deduced the same relations between the forces on charges by another approach, and this important relation is now known as Coulomb's law.

Coulomb's law may be stated in words as follows: In a homogeneous, isotropic medium the force of attraction or repulsion between two charges of electricity concentrated at two points that are small compared to the distance between them is proportional to the product of their charge magnitudes, inversely proportional to the square of the distance between the charges, and inversely proportional to a characteristic constant of the medium in which the charges reside, called its "permittivity." The force between unlike charges is one of attraction; the force between like charges is one of repulsion.

Mathematically, Coulomb's law may be stated in the form

$$f = K_e K' \frac{Q_1 Q_2}{\epsilon l^2} = K_e K' \frac{Q_1 Q_2}{\epsilon_0 \epsilon_r l^2}$$

where, in mks units, f is the force in newtons exerted by the two charges on one another, Q_1 and Q_2 are the two charges in coulombs, $\epsilon = \epsilon_0 \epsilon_r$ is a physical property of the homogeneous isotropic medium known as the *permittivity* and is measured in farads per

factors given in Table 13. The question of rationalization was left open by the IEC so that, at the present time, there is no unanimity as to which set of equations should be free from the unavoidable constant, 4π, representing the number of solid radians in a closed surface. In this section, K coefficients, with suitable primes, are used to replace coefficients involving the factor 4π. By inserting the appropriate value of K, as given in Table 6, the equations in this section are directly applicable to either the unrationalized or the rationalized system.

meter, ϵ_0 is the permittivity of free space (vacuum) measured in farads per meter, ϵ_r is a numeric expressing the ratio of the permittivity of any substance to the permittivity of free space, l is the distance between the point charges in meters, K_e is a constant which depends upon the units in which the force and charge are measured, and K', whose value is given in Table 6, is a constant whose value depends upon whether the unrationalized or the rationalized system of equations is employed.

Table 6. Factors for Rationalized and Unrationalized Systems of Units

Factor	Value in unrationalized system	Value in rationalized system
K'	1	$\frac{1}{4\pi}$
K''	$\frac{1}{4\pi}$	1
K'''	4π	1
K''''	1	4π

Coulomb's law provides a basis for relating mechanical units (of force) with electrical units (of charge). Another important result of Coulomb's law and the specification of the charge in terms of multiples of the elementary charge ($Q = ne$) is that the mechanical forces produced by charges may be accounted for by the linear superposition of charges, for multiplying one of the charges by any quantity (keeping the other charge constant) multiplies the resulting force by the same quantity. It makes no difference which charge is kept constant and which is varied; hence, it follows that charges may be combined in any order. This statement applies whether the charges are stationary or in motion so that the principle of linear superposition also applies to electric currents (which are charges in motion) so long as the medium is homogeneous and isotropic.

95. Conservative Properties of Static Fields. Problems in electrostatics may be solved by the fundamental relations expressed by Coulomb's law, which deals with forces that have direction as well as magnitude. The calculation of directed forces is a laborious and tedious undertaking, so that, except in the simplest configurations of charges, calculations by Coulomb's law become too cumbersome for general use. The concept of potential greatly simplifies problems in electricity by eliminating the need to consider direction (except in a positive and negative sense). Since the potential concept is applicable only to conservative fields, it is necessary to ascertain that the electrostatic field is conservative, *i.e.*, that the energy of an electrostatic field is a function of position only and does not depend upon the path that the charge takes between the two points.

According to Coulomb's law and the definition for work, the increment of work done in moving a charge a distance dr is given by the equation[1]

$$dw = -\mathbf{f}\cos\theta\, dl = -\mathbf{f}\cdot dr = -(K_e K' Q_1 Q_2/\epsilon r^2)\, dr$$

[1] When vector quantities are encountered, it is frequently necessary to express physical quantities in terms of the component of the vector that is along a specified path or is normal to a specified surface. For example, the increment of work is equal to the product of the distance through which a body moves by the component of force in the direction of motion, or $dw = \mathbf{f}\cos\theta\, dl$, where $\mathbf{f}$ is the force, dl is the element of length in the direction of motion, and θ is the angle between the direction of the force and the direction of motion. Thus, $\mathbf{f}\cos\theta$ is that component of the force in the direction of motion along dl. In cases such as this, the desired vector (in this example, the element of work) may be expressed in any of the alternative ways

$$\mathbf{f}\cos\theta\, dl = \mathbf{f}\cos(\mathbf{f}, l)\, dl = \mathbf{f}\cdot dl$$

where the notation $(\mathbf{f}, l)$ represents the angle between the direction of $\mathbf{f}$ and that of l. The dot (·) is used to represent the cosine of this angle, or $\cos\theta$.

The vector $\mathbf{f}$ may be resolved into its components along any set of three coordinates in space. Each such component is, of course, a vector quantity and may be specified in terms of its component vectors in the direction of each coordinate. Thus, the vector $\mathbf{f}$ may be resolved, for example, into its rectangular coordinate components, $\mathbf{f}_x$, $\mathbf{f}_y$, and $\mathbf{f}_z$, as in the expression

$$\mathbf{f} = \mathbf{f}_x + \mathbf{f}_y + \mathbf{f}_z$$

A vector may also be specified in terms of a unit vector in the direction of each coordinate and a scalar quantity representing the magnitude of the vector component along each coordinate. Thus, if $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ are unit vectors in the x, y, and z directions, respectively, and if f_x, f_y, and f_z are the magnitudes

the negative sign being used because positive work is done in moving the charge in the $-r$ direction. The total amount of work done in moving the charge from any point A to any other point B whose distances from any reference point are r_A and r_B, respectively, is then the integral of dw between the two points, or

$$w = w_A - w_B = \int_B^A dw = -\int_{r_B}^{r_A} \left(\frac{K_e K' Q_1 Q_2}{\epsilon r^2}\right) dr = -\left(\frac{K_e K' Q_1 Q_2}{\epsilon r}\right)\left(\frac{}{r_A} - \frac{1}{r_B}\right)$$

This result is independent of the path taken between A and B and depends only upon the positions of the end points of the path traversed. Therefore, the electrostatic field is conservative.

96. Electrostatic Potential. The electric potential difference between two points in an electrostatic field is equal to the work associated with the transfer of unit quantity of positive charge from one point to another. The maximum amount of work is done by (or on) charges that move along the lines of electric force, whereas no work is done by (or on) a charge that moves perpendicular (normal) to lines of electric force. If A and B are the two points between which a unit positive charge is transferred, then B is at a higher potential than A if external energy is required to transfer unit positive charge from A to B.

The great advantage of the concept of potential is that, through its use, vector calculations of the forces acting on charges may be resolved into scalar calculations which are much simpler to manipulate. From the definition given above, it is evident that there exists only a means for determining the difference or change of potential between two points and not for determining the absolute value of the potential of any point. If it is possible to establish as an arbitrary reference an equipotential surface, *i.e.*, a surface normal to the lines of force upon which no work is required to transfer a positive charge from one point to another on the surface, this surface may be established or defined as being at zero potential. The potential of any point may then be specified relative to the equipotential surface arbitrarily designated as being at zero potential. In engineering work the earth is often arbitrarily taken as the zero reference equipotential surface, and potential differences are then measured relative to the potential of the earth's surface. In other cases, particularly in theoretical work, it is convenient to assign zero potential to a sphere of infinite radius, since the force produced at a point infinitely removed from a charge is zero.

The increment of work per unit charge that is done in moving the charge a distance dl in an electric field is $dw_Q = -(f/Q)\cos\theta\, dl$. But by definition, $\mathcal{E} = f/Q$ and, therefore, $dw_Q = -\mathcal{E}\cos\theta\, dl$. The difference in potential between two points A and B is the integral along the path from A to B, or

$$E_{AB} = V_A - V_B = -\int_B^A \mathcal{E}\cos\theta\, dl = -\int_B^A \mathcal{E}\cdot dl$$

(scalar quantities) of **f** in these three directions, the vector may be expressed in the alternative form

$$\mathbf{f} = \mathbf{i}f_x + \mathbf{j}f_y + \mathbf{k}f_z$$

The vector may represent a quantity flowing through a surface. For example, the amount of liquid that passes outward through the element of surface, ds, in unit time at any point on the surface is the product of the outward normal (or perpendicular) component of the vector **F** and the surface element, ds. If **n** is a unit vector normal to the surface elements, ds, the outward flow of liquid may be expressed in any of the alternative ways

$$\mathbf{F}\cos\theta\, ds = \mathbf{F}\cos(\mathbf{F}, n)\, ds = \mathbf{F}\cdot n\, ds = \mathbf{F}_n\, ds$$

where $(\mathbf{F}, n)$ represents the angle between the direction of **F** and the surface normal, n. The dot (·) expresses the cosine of the angle between **F** and n, and $\mathbf{F}_n$ is the component of **F** perpendicular to the surface element.

In some texts, especially those stressing vector notation, vector quantities are printed in boldface (heavy) type, as has been done for illustration in this footnote. In other cases, as in the main text of this section, ordinary light-face characters are employed. In this section script letters have been used for those electrical quantities (as $\mathcal{E}$, $\mathfrak{D}$, $\mathcal{H}$, and $\mathcal{B}$) which are regarded as vectors in space.

where V_A is the absolute potential of point A, V_B is the absolute value of potential of point B, $E_{AB} = V_A - V_B$ is the difference in potential between points A and B, $\mathcal{E}$ is the electric intensity in the region along the path from A to B, and θ is the angle between the direction of $\mathcal{E}$ and that of dl. Although absolute values for V_A and V_B are not known, the difference $V_A - V_B$ can be ascertained.

If A and B are the two points between which a positive charge is transferred, then B is at a higher potential than A if external work is done in transferring the charge from A to B, *i.e.*, if energy is expended to effect this transfer. Point B is then said to be at a higher potential than point A; alternatively, point B is said to be positive with respect to point A. Energy is given up when the positive charge is transferred from B to A.

In the mks system of units, unit potential difference is the joule per coulomb, which has been given the name *volt*.

If the electrostatic field is made up of concentrated charges $Q_1, Q_2, Q_3, \ldots, Q_n$ in a homogeneous isotropic medium whose permittivity is ϵ and in which the distances of these charges from a point P are $r_1, r_2, r_3, \ldots, r_n$ and if the potential of a sphere infinitely distant is regarded as the reference or zero potential, then, with respect to the zero reference potential, the potential of the point P is

$$E_P = -\int_\infty^{r_1} \frac{K_eK'Q_1}{\epsilon r_1^2}\,dr - \int_\infty^{r_2} \frac{K_eK'Q_2}{\epsilon r_2^2}\,dr - \int_\infty^{r_3} \frac{K_eK'Q_3}{\epsilon r_3^2}\,dr - \cdots - \int_\infty^{r_n} \frac{K_eK'Q_n}{\epsilon r_n^2}\,dr$$

$$= -\frac{K_eK'}{\epsilon}\left(\frac{Q_1}{r_1} + \frac{Q_2}{r_2} + \frac{Q_3}{r_3} + \cdots + \frac{Q_n}{r_n}\right)$$

$$= -\frac{K_eK'}{\epsilon}\sum_{n=1}^{m} \frac{Q_n}{r_n}$$

In practice such an expression as that given above is applicable only if a very small number of charges is encountered, for the calculations become tedious and cumbersome if many charges must be taken into account.

When many charges make up an electrostatic field, it is often convenient to disregard the individual charges and deal with their net or over-all effects as expressed by the density of charge. If σ is the surface charge density and ρ is the volume charge density, then the charge distributed over an elementary area, ds, is $dQ = \sigma_n\,ds$ and the charge distributed throughout an elementary volume, dv, is $dQ = \rho\,dv$. In the case of a continuous distribution of charge throughout a volume and also over a surface, the potential of the point P (with respect to zero potential at a point infinitely remote), whose distance from the volume and the surface is r, is given by

$$E_P = \iint_s \frac{dQ}{r} + \iiint_v \frac{dQ}{r} = \iint_s \frac{\sigma_n\,ds}{r} + \iiint_v \frac{\rho\,dv}{r}$$

The electrostatic potential (defined as the work per unit charge done in, or available for, transporting electric charges) is applicable to static fields. The concept of potential may be generalized and applied to fields in which the charges vary with time. The potential field is a scalar field whereas the field of force is a vector field.

97. Potential Gradient. The gradient of a scalar field at a point is a vector whose magnitude is equal to the space rate of change of the scalar field in the direction of greatest increase and whose direction is that of the greatest increase. This general definition may be applied to the potential field as follows:

From the relations given in Sec. 96 it is easy to show that $dE = -\mathcal{E}\cos\theta\,dl$, from which $\mathcal{E}\cos\theta = -(dE/dl)$. If the direction of the field of force exerted on a small positive test charge is in the direction of the element of path length, dl, then $\cos\theta = 1$. For this condition the change of potential is a maximum with respect to a change of position. The maximum rate of change of potential with position is a vector quantity

whose direction is at right angles to the equipotential surface or along the electric lines of force; it is called the "potential gradient" and is abbreviated "grad E." Hence, from the results above,

$$\text{grad } E = \frac{dE}{dl} = -\mathcal{E}$$

In the mks system of units, the gradient is measured in volts per meter.

The potential gradient may be resolved into orthogonal components. In rectangular coordinates,

$$\text{grad } E = \nabla E = \left(\mathbf{i}\frac{dE_x}{dx} + \mathbf{j}\frac{dE_y}{dy} + \mathbf{k}\frac{dE_z}{dz}\right) = -(\mathbf{i}\mathcal{E}_x + \mathbf{j}\mathcal{E}_y + \mathbf{k}\mathcal{E}_z)$$

where **i**, **j**, and **k** are unit vectors in the x, y, and z directions, respectively, and the components of E and $\mathcal{E}$ in each of the rectangular coordinate directions are indicated by the subscript x, y, or z.

A pictorial representation of potential gradient resolved into its orthogonal components in rectangular coordinates is given in Fig. 26. The potential gradient is, strictly speaking, applicable to the field intensity only in the case of an electrostatic field.
FIG. 26. Potential gradient at point P in terms of its orthogonal components, expressed in rectangular components.
FIG. 27. Determination of electric flux diverging from a closed surface. The total flux is the sum of all components normal to a closed surface.

98. Electric Flux. Consider a surface element at a point in an electric field for which the electric intensity is $\mathcal{E}$. If θ represents the angle between the direction of $\mathcal{E}$ and the normal to the surface, **n**, then, as shown in Fig. 27 the component of $\mathcal{E}$ perpendicular to the surface is $\mathcal{E} \cos \theta = \mathcal{E} \cos (\mathcal{E}, n) = \mathcal{E} \cdot n = \mathcal{E}_n$. The product of the normal component of the electric field intensity and the surface is called the "electric flux." The electric flux, represented by the symbol ψ, may be represented by lines that are drawn in the same direction as the lines of electric intensity but of such spacing that their density (in lines per unit area) perpendicular to the direction in which the lines run is equal to the dielectric flux density at the point at which the flux is measured. From a physical point of view, the electric flux may be regarded as the number of lines of electric field that cross perpendicular to a surface; it is the total number of such lines and not the density in lines per unit area.

Electric flux is a scalar quantity, the sign of which depends upon the assumption made concerning the positive direction of the normal. With a closed surface, the outward normal is taken as positive. For an open surface, if the positive sense is that in which the periphery of the surface is described by the rotation of a right-hand screw normal to the surface, the positive direction of the normal is that in which the screw advances.

In the mks system of units, the electric flux, ψ, is measured in coulombs, the same unit in which charge is measured. In the unrationalized system, the magnitudes of the units of electric flux and charge are the same, but in the rationalized system the unit of electric flux is $1/4\pi$ as large as in the unrationalized system.

99. Electric Displacement; Electric Flux Density. The electric displacement, or the electric flux density, at any point in an isotropic dielectric medium is a vector having the same direction as that of the electric field intensity, and a magnitude that is ϵ times that of the electric field intensity. If, in mks units, $\mathcal{E}$ is the electric field intensity in volts per meter, $\mathfrak{D}$ is the electric displacement in coulombs per square meter, and ϵ is the permittivity of the dielectric medium in farads per meter, then the electric flux density in an isotropic dielectric is

$$\mathfrak{D} = K''\epsilon\mathcal{E}$$

Thus, the displacement takes into account the permittivity properties of the medium through which the lines of electric flux flow; the properties of the medium are inherent in the displacement vector itself.

If $\mathfrak{D}$ represents the electric displacement vector making an angle θ with the surface through which the electric field passes, then the element of electric flux crossing an element of surface is

$$d\psi = \mathfrak{D} \cos \theta \, ds = \mathfrak{D} \cos (\mathfrak{D}, s) \, ds = \mathfrak{D}_n \, ds = \mathfrak{D} \cdot ds$$

The total flux is the integral over the closed surface through which flux passes, or

$$\psi = \iint_s \mathfrak{D} \cos \theta \, ds = K'''Q$$

where, in mks units, ψ is the electric flux in coulombs, $\mathfrak{D}$ is the displacement in coulombs per square meter, and ds is an element of surface, expressed in square meters. This equation merely states that the total flux diverging from a closed surface is proportional to the total charge enclosed by the surface, as shown in Fig. 28.

100. Dielectric Polarization. For a material dielectric the displacement, $\mathfrak{D}$, may be split into two parts

$$\mathfrak{D} = \epsilon\mathcal{E} = \epsilon_0\epsilon_r\mathcal{E} = \epsilon_0\mathcal{E} + (\epsilon_r - 1)\epsilon_0\mathcal{E}$$

The first term, $\epsilon_0\mathcal{E}$, is the displacement for free space. The second term, $(\epsilon_r - 1)\epsilon_0\mathcal{E}$, represents an actual displacement or shift of bound electric charges within the material dielectric itself. This latter displacement or shift is customarily measured in units of charge per unit area, or in mks units, in coulombs per square meter; it is called the "polarization" of the dielectric and is designated by the symbol $\mathcal{P}$. Since the unit of displacement is K' times the unit of charge, $(\epsilon_r - 1)\epsilon_0 = 4\pi$ so that

$$\mathfrak{D} = \epsilon_0\mathcal{E} + 4\pi\mathcal{P}$$

101. Gauss's Theorem. Coulomb's law is one of the most important of all electrical laws and one way of expressing the relation between charge and force has already been given for an isotropic, homogeneous medium. The inverse-square law, already given, is the form that is most convenient in providing a quantitative idea of the forces between isolated electric charges, but Coulomb's law may also be given in alternative forms that bring out certain additional general and important properties of charged bodies and facilitate many kinds of calculations. Gauss's theorem is one highly important alternative expression for Coulomb's law. The diagram of Fig. 28 illustrates the theorem.

Gauss's theorem makes use of the concept of electric flux. The theorem may be stated in words as follows: The integral, over any closed surface, of the normal component of the electric flux density or displacement is equal to the charge contained

within the surface. In mathematical notation this may be expressed as

$$\psi = \oint\!\!\oint_s \epsilon \mathcal{E} \cos \theta \, ds = \oint\!\!\oint_s \mathfrak{D} \cos \theta \, ds = \iiint_v \rho \, dv = K'''Q$$

where $\mathfrak{D}$ is the electric flux density in coulombs per square meter, $\mathcal{E}$ is the electric field intensity in volts per meter, θ is the angle between the direction of $\mathfrak{D}$ or $\mathcal{E}$ and the normal to the surface, ds is an element of surface expressed in square meters, ρ is the volume charge density in coulombs per cubic meter, and dv is an element of volume expressed in cubic meters.
FIG. 28. Total electric flux diverging from a closed surface (left) is equal to the total charge enclosed by that surface.

The above equation is the integral form of Gauss's theorem, which may be derived as follows. If the electric displacement, $\mathfrak{D}$, crosses a surface element, ds, the normal component of flux density crossing the surface is

$$d\psi = \mathfrak{D} \cos \theta \, ds = \epsilon \mathcal{E} \cos \theta \, ds = [Q \, (\cos \theta)/r^2] \, ds$$

But $[(\cos \theta)/r^2] \, ds$ is an elementary solid angle, $d\Omega$, and, hence, $d\psi = Q \, d\Omega$. Hence the total flux is the integral over a closed surface, and since there are 4π radians in a closed surface, the flux is given by

$$\psi = \oint\!\!\oint_s Q \, d\Omega = K''Q$$

102. Equations of Laplace and Poisson. Gauss's theorem may be put into differential as well as integral form to obtain either the Laplace or the Poisson equation. The differential form may be obtained by resolving the electric flux into three orthogonal components, expanding each component in a Taylor's series expansion and forming the algebraic sum of the linear terms in this expansion for each orthogonal component, over a closed surface. If the volume enclosed is free from charge, the result of such an operation is the scalar quantity given by Laplace's equation,

$$\text{div } \mathfrak{D} = \frac{d\mathfrak{D}_x}{dx} + \frac{d\mathfrak{D}_y}{dy} + \frac{d\mathfrak{D}_z}{dz} = 0$$

whereas if the enclosed volume has a volume charge density, ρ, the equation of Poisson results,

$$\text{div } \mathfrak{D} = \frac{d\mathfrak{D}_x}{dx} + \frac{d\mathfrak{D}_y}{dy} + \frac{d\mathfrak{D}_z}{dz} = K'''\rho$$

The equations of Laplace and Poisson may be expressed in terms of potential as well as of electric field intensity since $\mathcal{E} = -(dE/dl)$. Hence the above equations become

$$\frac{d^2E_x}{dx^2} + \frac{d^2E_y}{dy^2} + \frac{d^2E_z}{dz^2} = 0$$

$$\frac{d^2E_x}{dx^2} + \frac{d^2E_y}{dy^2} + \frac{d^2E_z}{dz^2} = -\frac{K'''\rho}{\epsilon}$$

Like the integral forms for expressing Gauss's theorem, the equations of Laplace and Poisson are merely alternative ways of expressing the fundamental laws of charge which were first quantitatively observed by Cavendish and Coulomb.

103. Divergence. Divergence is a concept that is useful in describing the flow of a quantity. The divergence of a vector field at any point may be defined as a scalar quantity equal in magnitude to the limiting ratio of the outward flux, passing through a closed surface that surrounds the point, to the volume enclosed within the surface, as the volume approaches zero. Physically the operation denoted by divergence yields a measure of the flux produced per unit volume, at a point. When flux flows away from a point, divergence is indicated; when it flows toward a point, negative divergence (sometimes called "convergence") is indicated.

If, in a vector field, the vector **A** is expressed in terms of its three rectangular orthogonal coordinates, A_x, A_y, and A_z, given as functions of x, y, and z coordinates, respectively, the divergence of the vector field is a scalar quantity formed by the sum of the derivatives of each orthogonal component in the direction of its axis, or

$$\text{div } \mathbf{A} \equiv \nabla\cdot\mathbf{A} \equiv (\nabla\mathbf{A}) = \frac{dA_x}{dx} + \frac{dA_y}{dy} + \frac{dA_z}{dz}$$

$$= \left(\mathbf{i}\frac{d}{dx} + \mathbf{j}\frac{d}{dy} + \mathbf{k}\frac{d}{dz}\right)(\mathbf{i}A_x + \mathbf{j}A_y + \mathbf{k}A_z)$$

As an example of this concept, the divergence of the electric intensity, which is proportional to the volume density of charge at the point, may be cited.

104. Curl. Curl is a concept useful in describing the rotation or swirl of a flowing quantity. The curl (also called "rotation," especially by European authors) of a vector field at a point is a vector whose magnitude is equal to the limiting ratio of the circuitation around a surface element on which the point is located, to the area of the surface as the latter approaches zero, provided the surface is so oriented as to give the maximum values of circuitation. The positive direction of this vector is that traveled by a right-hand screw turning about an axis normal to the surface element when the turning of the screw gives a positive value to the circuitation or rotation.

If the vector **A** of a vector field is expressed in terms of its three rectangular components, A_x, A_y, and A_z, given as functions of x, y, and z, respectively, the curl of the vector field is the vector sum of the partial derivatives of each component with respect to the axes perpendicular to it. Mathematically,

$$\text{curl } \mathbf{A} \equiv \nabla \times \mathbf{A}$$

$$= \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ \frac{\partial}{\partial x} & \frac{\partial}{\partial y} & \frac{\partial}{\partial z} \\ A_x & A_y & A_z \end{vmatrix} = \mathbf{i}\left(\frac{\partial A_z}{\partial y} - \frac{\partial A_y}{\partial z}\right) + \mathbf{j}\left(\frac{\partial A_x}{\partial z} - \frac{\partial A_z}{\partial x}\right) + \mathbf{k}\left(\frac{\partial A_y}{\partial x} - \frac{\partial A_x}{\partial y}\right)$$

where **i**, **j**, and **k** are unit vectors along the x, y, and z axes, respectively.

As an example of the curl concept, the magnetic intensity at a point within an electric conductor, which is proportional to the current density, may be cited.

MAGNETOSTATICS

105. Definition. Magnetostatics is the branch of science that deals with the laws of permanent magnets. Prior to the discovery by Oersted in 1820 of the relation between electricity and magnetism, the study of magnetostatics was pursued independent of that of electrostatics, for in the static case no relation between electrostatics and magnetostatics can be made at all apparent. With the discovery that the flow of electric currents produced magnetic fields, there arose an attempt to explain all magnetic phenomena in terms of the flow of an electric current. Some authors have justified this point of view on the ground that, although the elementary electric charge has been discovered, no corresponding magnetic charge or pole has been observed as an entity of nature.

There is ample evidence that magnetic effects are the result of the flow of an electric current and possibly some justification for omitting a treatment of magnetostatics. Such a course overlooks the fact that many existing texts already employ the concepts of magnetostatics; it also neglects the historical approach which has given rise to much confusion in the establishment of electrical units.

106. Magnets. A magnet is a body or substance that produces a magnetic field external to itself. The first known magnets were natural magnets of lodestone, but today magnets for practical purposes are made of iron, steel, or alloys in which the principal constituents are usually iron, nickel, cobalt, and perhaps small proportions of other metals such as aluminum or copper.

A magnetic field is a vector field of force imparting, or tending to impart, motion to fine particles of a magnetic substance (*e.g.*, iron filings) situated in the magnetic field.

107. Magnetic Pole. The magnetic poles (or simply the poles) of a magnet are those portions of a magnet toward which the external magnetic field tends to converge or from which it tends to diverge. Magnetic poles always occur in pairs; they cannot be isolated as can electric charges. The size and position of the poles of a magnet depend upon its shape and also upon its magnetic characteristics. For a magnet that is long and slender (as a steel needle), the poles are located at small regions near the ends. In such a case the poles are virtually points, and it is convenient to regard them as concentrated at points.

A study of magnetostatics may be built up on the hypothesis that magnetic poles can be considered to exist in complementary pairs. The mathematics of magnetostatics then becomes very similar to the mathematics of electrostatics, but a different physical interpretation of the equations is required because isolated magnetic poles have not been identified.

108. Coulomb's Law for Magnetic Poles. Experiment shows that for long, thin, magnetized needles, the poles may be regarded as being concentrated at points near their ends. The regions at which the magnetic effects are concentrated may then be regarded as isolated magnetic poles each of which establishes its own spherical magnetic field of force, much as isolated charges establish their spherical electrical field of force. This point of view is justified by the mathematical convenience of the equations of magnetostatics (and the similarity of the equations of magnetostatics to those of electrostatics) rather than by the precision with which this view accords with physical facts. If such a view is adopted, the force between magnetic poles obeys the inverse-square law, and Coulomb's law may be applied to magnetic poles as well as to electric charges.

Coulomb's law for magnetic poles may be stated as follows: In a homogeneous, isotropic medium, the force between two magnetic poles that are small compared to the distance between them is proportional to the product of the magnitudes (or strengths) of the two poles, inversely proportional to the square of the distance between them, and inversely proportional to a characteristic property of the medium in which the

poles reside, called its "permeability." The force between unlike poles is one of attraction; the force between like poles is one of repulsion.

Mathematically, Coulomb's law for magnetic poles may be stated as

$$f = K_m K' \frac{M_1 M_2}{\mu l^2} = K_m K' \frac{M_1 M_2}{\mu_0 \mu_r l^2}$$

where, in mks units, f is the force in newtons exerted between the two poles, M_1 and M_2 are the magnitudes of the pole strengths of the two magnetic poles, $\mu = \mu_0 \mu_r$ is a physical property of the homogeneous, isotropic medium in which the poles reside, called the *permeability* of the medium, μ_0 is the permeability of free space (vacuum) measured in henrys per meter, μ_r is a numeric expressing the ratio of the permeability of any material substance to that of free space, l is the distance between the two poles in meters, K_m is a constant relating pole strength and mechanical units of force, and K' is a constant which adapts the equation to the rationalized or unrationalized system and whose value is given in Table 6.

With the exception that no free, isolated, magnetic poles exist (so that, for example, there is no magnetostatic equivalent of the electrostatic charge density), the reasoning developed for electric charges applies to magnetic poles. Thus, Gauss's theorem and the equation of Laplace apply to magnetic poles as well as to electric charges, but Poisson's equation becomes identical with Laplace's since there is no magnetic "pole density."

109. Pole Strength. The strength of a magnetic pole that can be considered as concentrated at a point is measured by the force exerted on the pole when it is placed in a magnetic field of known intensity in a vacuum. A unit magnetic pole is one which is concentrated at a point and which has such strength that, when placed at a unit distance from an exactly similar pole, it will experience a unit repelling force. In the cgs electromagnetic units, the unit of pole strength is the pole, but this unit has no name in the cgs electrostatic or in the mks system of units.

110. Magnetic Field Intensity. The magnetostatic field intensity due to a magnetic pole is defined as a vector whose magnitude is equal to the force per unit magnetic pole strength exerted on a test body, and whose direction is the same as the direction of the force exerted on the test body. The test body is a concentrated north-seeking pole of such small strength (strictly, infinitesimal strength) that its presence does not alter the magnetic field that it is intended to measure.

The magnetic field intensity may be defined by the magnetostatic relation,

$$\mathcal{H} = \lim_{\Delta M \to 0} \frac{\Delta f}{\Delta M}$$

where, in the mks system of units, $\mathcal{H}$ is measured in ampere-turns per meter, f is the force in newtons, and M is the pole strength. This equation is analogous to the electric field intensity produced by static electric charges. The magnetic field intensity may also be defined by a dynamic relation in terms of current flow (see Sec. 127).

The direction and magnitude of the magnetic field intensity may be represented by lines of magnetic force, just as lines of electric force represent the direction and magnitude of the electric field intensity.

111. Magnetic Flux. The magnetic flux, ϕ, produced by magnetic poles, through a surface may be regarded as the number of lines of magnetic force that cross perpendicular to the surface. It is a scalar quantity, derived in a way completely similar to that by which electric flux is derived. In the mks system of units, the magnetic flux is measured in webers.

112. Magnetic Induction; Magnetic Flux Density. The magnetic induction, or the magnetic flux density, at any point in a magnetic field is a vector whose magnitude is μ times that of the magnetic field intensity, $\mathcal{H}$, and whose direction is that of the magnetic field intensity. If $\mathcal{H}$ is the magnetic field intensity and μ is the permeability

of the magnetic medium, then the magnetic induction (or magnetic flux density) is given by the relation

$$\mathcal{B} = \mu\mathcal{H}$$

In mks units the magnetic induction is measured in webers per square meter.

In terms of the magnetic flux density, the magnetic flux is given by

$$\phi = \iint_s \mathcal{B} \cos\theta \, ds$$

where θ is the angle between the direction of $\mathcal{B}$ and the normal to the surface element. Over a closed surface,

$$\phi = \oiint_s \mathcal{B} \cos\theta \, ds = 0$$

This relation may be regarded as a result of the absence of free, isolated magnetic poles. Permanent magnets, however small, are always found in equal and opposite pairs. Therefore, for any volume containing a permanent magnet, as many lines of magnetic force leave the surface of enclosure as enter it; so the net or resultant flux is zero. In mks units, ϕ is the magnetic flux in webers, $\mathcal{B}$ is the magnetic flux density in webers per square meter, ds is an elementary surface area expressed in square meters, and θ is the angle between the direction of the flux density and the normal to the element of surface, ds.

In differential form, Gauss's theorem for magnetic flux density is given by

$$\frac{d\mathcal{B}_x}{dx} + \frac{d\mathcal{B}_y}{dy} + \frac{d\mathcal{B}_z}{dz} = 0$$

In words, the divergence of magnetic flux from a closed surface is zero.

113. Magnetization. Magnets are regarded as being produced by the proper alignment or orientation of elementary magnets (of crystalline dimensions) within the crystalline structure of the magnetic material. In the natural state the elementary magnets are at random orientation; hence, the substance shows no magnetic properties. As more and more of the elementary magnets assume the same orientation, the magnetism increases, up to the limit attained when all elementary magnets are aligned in the same direction.

The magnetic properties of material substances may be separated from those of free space in the same way in which dielectric polarization was separated from the permittivity of free space. Thus, we may write

$$\mathcal{B} = \mu\mathcal{H} = \mu_0\mu_r\mathcal{H} = \mu_0\mathcal{H} + (\mu_r - 1)\mu_0\mathcal{H} = \mu_0\mathcal{H} + 4\pi\mathfrak{M}$$

where $\mathfrak{M}$ is the intensity of magnetization, which, in the mks system, is measured in webers per square meter.

114. Permeability and Reluctivity. Permeability, designated by the symbol μ, is the property of an isotropic medium which determines, under specified conditions, the magnitude relation between magnetic induction and magnetic intensity (also called "magnetizing force") of the medium.

Under the specified conditions, permeability is measured as the ratio of the magnetic induction to the magnetic intensity. Mathematically, the permeability is defined to be

$$\mu = \frac{\mathcal{B}}{\mathcal{H}}$$

Reluctivity of a medium is the reciprocal of its permeability. Mathematically,

$$\nu = \frac{1}{\mu} = \frac{\mathcal{H}}{\mathcal{B}}$$

ELECTRODYNAMICS

115. Definition. Thus far we have dealt with electric charges and magnetic poles in the static case; *i.e.*, we have dealt with charges and poles free from motion relative

to the reference coordinate system. So long as only static conditions were studied, there were no discernible connections between electricity and magnetism. With the discovery, in 1820, by Oersted (quickly repeated by Ampère) that the flow of an electric current produced a magnetic field, and the further discovery by Faraday in 1831 that a varying magnetic field was capable of producing an induced electromotive force, the connection between electricity and magnetism was clearly and firmly established, and from then on the unified subject of electromagnetism was studied.

Electromagnetism may be defined as the study of electricity (electric charges) in motion, the magnetic effects produced by the flow of electricity, and, conversely, the electrical effects arising from the relative motion of a magnetic field and path through which electric current may pass or flow. The current may be a conduction current or a displacement current. In the former case, electromagnetic energy may be guided between two points connected by a conductor. In the latter case, electromagnetic energy may be transferred from one point to another through a dielectric.

The term "electrodynamics" (or electrokinetics) is used in place of electromagnetism, particularly when the motional aspect of the electric charges is emphasized, as in distinguishing electrostatics from electrodynamics. The term "electromagnetism" usually includes electrostatics and, hence, is often regarded as a more encompassing term than "electrodynamics."

116. Electric Current. An electric current through a surface is the time rate at which positive or negative charges pass through it. If both positive and negative charges are simultaneously passed through the surface, the current is the time rate of passage of the algebraic sum of the two. Three types of current flow are recognized: conduction current, convection current, and displacement current.

A conduction current comprises the movement of negative charges (electrons) exclusive of any movement due to the transportation of negative electricity by masses larger than electrons. A convection current is a current in which the charges are electrified particles larger than electrons. The displacement current through any surface in an isotropic dielectric is proportional to the time rate of change of the displacement flux through the surface.

In accordance with these definitions, the conduction and convection currents may be regarded as the flow of physical particles through a surface, the magnitude of the current being proportional to the net flow of the charged particles transported through the surface. No charge can pass through an ideal dielectric, and yet the time-varying charges accumulating on the plates of a capacitor give every indication that their physical presence is equivalent to the flow of a time-varying current through the dielectric. The magnitude of this displacement current is proportional to the time rate of change of the electric flux between the two conductors of the capacitor. But such a time rate of change of electric flux exists in the case of conduction and convection currents as well. Instead of visualizing the electric current as the flow of actual particles through a surface, a more fundamental and basic point of view is to regard the electric current as the time rate of change of the electric flux produced by moving charges. If the charges are able to pass through a surface, then the effect is the usual one associated with a conduction current or with the continuous passage of charged particles. On the other hand, if the charges are prevented from crossing a surface (as in the case of the dielectric in a capacitor), the flow of displacement current is still permissible without any change in fundamental concepts. In any case, the total current flowing at any instant of time is the sum of the conduction, convection, and displacement components of current.

If Q represents the charge of moving charged particles, the conduction (or convection) current is given by

$$I_c = \frac{dQ}{dt}$$

whereas if $\psi = K'''Q = Q/K'$ is the electric flux produced by the charge Q and flowing through a surface, the displacement current through this surface due to the variation

of the electric flux is

$$I_d = K' \frac{d\psi}{dt}$$

The total current, composed of conduction (or convection) and displacement components, is

$$I_t = I_c + I_d = \frac{dQ}{dt} + K' \frac{d\psi}{dt}$$

In mks units, the charge and flux are measured in coulomb units, and the current (all components, individually or collectively) is measured in coulombs per second or in amperes.

117. Current Density. Current density at a point is a vector whose direction is the same as that of the current flow and whose magnitude is equal to the limiting ratio of the current flowing normally across the surface, as the surface becomes infinitesimally small. The current density represents the current flow per unit area at the point. In mediums that obey Ohm's law, the current density is proportional to the electric field intensity.

If s is the area surrounding the specified point at which the current flows, I is the magnitude of the current flowing, θ is the angle between the direction of current flow and the normal to the surface through which it flows, then the normal component of current across the surface is $I_n = I \cos \theta$, and the current density is defined to be

$$\mathcal{J} = \lim_{\Delta s \to 0} \frac{\Delta I_n}{\Delta s}$$

In the mks system of units, current is measured in amperes, area is measured in square meters, and current density is, therefore, measured in amperes per square meter.

In terms of the current density, the total current flowing across a surface, s, is

$$I = \iint_s \mathcal{J} \cos \theta \, ds = \iint_s \mathcal{J}_n \, ds = \iint_s \mathcal{J} \cdot ds$$

If $\mathcal{J}_c$ is the conduction (and convection) component of the current density, and $\mathcal{J}_d = K'(d\mathfrak{D}/dt)$ is the displacement component, the total current density is then $\mathcal{J}_T = \mathcal{J}_c + \mathcal{J}_d = \mathcal{J}_c + K'(d\mathfrak{D}/dt)$, and the normal component, flowing perpendicularly through a surface, is given by

$$\mathcal{J}_n = \left(\mathcal{J}_c + K' \frac{d\mathfrak{D}}{dt}\right)_n$$

where, in the mks system, $\mathcal{J}_n$ is measured in amperes per square meter.

118. Continuity of Current. From the fact that elementary charges are indestructible, we may conclude that an electric current is continuous and that electricity is conserved. Such is indeed the case. The proof of this statement is readily available.[1]

119. Electrical Conduction. The electric field intensity, $\mathcal{E}$, is the force that tends to move electric charges. Under the influence of such a force, a current density, $\mathcal{J}$, tends to flow in a conductor, the current density being represented by the time rate of flow of charges across an area perpendicular to the electric field intensity. The electric field intensity may then be viewed as the cause that produces or tends to produce a flow of conduction current density. There must, therefore, be some relation between $\mathcal{E}$ and $\mathcal{J}$ to express this cause-effect relation and, from what has been said about dielectrics and conductors, we might expect the results for these two cases to differ.

The relation between the electric field intensity and the current density cannot be obtained by simple reasoning alone; recourse must be made to experiment as well as to theory to obtain this relationship. Experiments show, however, that for homo-

[1] See, for example, such references as the following: R. W. P. King, "Electromagnetic Engineering," Vol. 1, McGraw-Hill, 1945; J. A. Stratton, "Electromagnetic Theory," McGraw-Hill, 1941; W. R. Smythe, "Static and Dynamic Electricity," McGraw-Hill, 1950.

geneous solids, this relationship is given by

$$\mathcal{J} = \sigma \mathcal{E}$$

where σ is a constant, characteristic of the material through which the electric field is established and through which the current flows, called the "conductivity" of the material. We may also obtain the correlation by means of the expression

$$\mathcal{E} = \rho \mathcal{J}$$

where $\rho = 1/\sigma$ is a characteristic of the material, known as its "resistivity." It should be observed that although the Greek letter sigma (σ) has been used for surface charge density as well as for conductivity, there is no connection between the two concepts expressed by the same symbol. Likewise, there is no connection between volume charge density and resistivity although both are expressed by the Greek rho (ρ). Little confusion will result because of the use of common symbols for different ideas, since the context will indicate which meaning is intended.

120. Conduction in Metals. Being an inherent property of a material to which an electric field is applied, the conductivity may be expected to be a function of the physical or chemical composition of the material, particularly with regard to those factors

Table 7. Resistivity and Temperature Coefficient of Resistivity of Common Electrical Conductors at t_0 = 20°C

Material	Resistivity, ohm-m	Temperature coefficient, A/°C
Aluminum	2.824×10^{-8}	0.0038
Antimony	41.7×10^{-8}	0.0036
Bismuth	120×10^{-8}	0.004
Brass	7×10^{-8}	0.001–0.002
Carbon	2.900×10^{-8}	−0.0005
Copper, annealed	1.724×10^{-8}	0.00393
Copper, hard-drawn	1.771×10^{-8}	0.00382
Gold	2.44×10^{-8}	0.0034
Iron	10.0×10^{-8}	0.0050
Mercury	95.783×10^{-8}	0.00089
Molybdenum	5.7×10^{-8}	0.0033
Nickel	7.8×10^{-8}	0.006
Platinum	10.0×10^{-8}	0.003
Silver	1.59×10^{-8}	0.0038
Tantalum	15.5×10^{-8}	0.00347
Thorium	40.1×10^{-8}	0.0021
Tungsten	5.6×10^{-8}	0.0045
Zinc	5.8×10^{-8}	0.00415

which determine or influence the relative freedom of motion of electrons within the material. This is, indeed, found to be true, so that the electrical conductivity or resistivity of a medium can be related to its characteristic atomic structure.

An elementary theory of metallic conduction[1] shows that the conductivity of a substance is given by the relation

$$\sigma = \frac{1}{2} \frac{l_m}{v_m} N e^2$$

where l_m is the mean free path of the electrons in the conductor, v_m is the average random velocity with which the electrons travel, N is the number of electrons in a length, l, of conductor of uniform cross section, and e is the charge of the electron. In mks units the conductivity is measured in mhos per meter. The resistivity, $\rho = 1/\sigma$, is measured in ohm-meters in the mks system of units.

The number of free electrons, N, in any given length of uniform conductor may be expected to be a function of temperature, so that the electrical properties of conductors

[1] Page, L., and N. I. Adams, "Principles of Electricity," p. 162, Van Nostrand, 1931.

are likewise a function of temperature. For metallic conductors, the resistivity increases with the temperature, but there are some materials, of which carbon is a notable example, in which the resistivity decreases with an increase of temperature. The resistivity of a homogeneous material may be expressed, as a function of temperature, by the expression

$$\rho = \rho_0[1 + A(t - t_0)]$$

where ρ_0 is the resistivity of the material at the specified or reference temperature, t_0, t is a temperature at which the resistivity is desired, and A is a constant, called the *temperature coefficient* of resistivity, typical values for which are given in Table 7.

121. Magnetic Field Produced by Electric Currents. Ampère's experiments on the magnetic intensity produced by an electric current showed that the magnetic field
FIG. 29. Lines of magnetic intensity around a current-carrying conducor are continuous, and the total magnetic flux crossing a closed surface is zero.

intensity produced at a point is proportional to the number of conductors, N, the current, I, in each conductor, the length, l, of the current-carrying elements, and the sine of the angle, θ, between the direction of the current element and the radius vector, $r = OP$, from the current-carrying element to the point P; it is also inversely proportional to the square of the distance, r, between the current-carrying element and the point of observation. Mathematically,

$$\mathcal{H} = \frac{NIl \sin \theta}{r^2}$$

where, in mks units, the magnetic field intensity, $\mathcal{H}$, is measured in ampere-turns per meter. From the relation $\mathcal{B} = \mu\mathcal{H}$, it follows that the magnetic flux density due to the flow of current through current-carrying elements is given by

$$\mathcal{B} = \frac{\mu(NIl \sin \theta)}{r^2}$$

where $\mathcal{B}$ is measured in webers per square meter in mks units.

Lines of magnetic intensity surrounding a current-carrying conductor are represented in the diagram of Fig. 29.

122. Divergence of Magnetic Flux. For a magnetic field produced by the flow of an electric current, as well as in the magnetostatic case, the magnetic flux is given by

$$\phi = \iint_s \mathcal{B} \cos \theta \, ds$$

where θ is the angle between the direction of $\mathcal{B}$ and the normal to the surface element, ds. Over a closed surface,

$$\phi = \oiint_s \mathcal{B} \cos \theta \, ds$$

i.e., the divergence of the magnetic flux, over a closed surface, is zero. This is represented diagrammatically in Fig. 29 by the illustration showing as many lines of magnetic intensity entering as leaving a small volume containing the current-carrying element.

123. Magnetic Force Produced by Current Elements. If a conductor of N turns, through which current I flows, lies in a magnetic field whose flux density is $\mathcal{B}$ webers per square meter, the force exerted on the conductor is given by the relation

$$f = \mathcal{B}NIl \sin \theta$$

where θ is the angle between the direction of $\mathcal{B}$ and that of l.

Since a magnetic field can be produced by the flow of current through conductors, and further since a current-carrying element in a magnetic field has a force exerted upon it, it follows that a mechanical force must exist between two current-carrying conductors.

124. Force between Current-carrying Elements. It has been shown (Sec. 121) that a current-carrying circuit element establishes a magnetic field and (Sec. 123) that a force is exerted on a conductor carrying a current in a magnetic field. Therefore, if two conductor elements each carry an electric current, each will be in the magnetic field produced by the other; hence, a force will be exerted between the two. The force between these two elements is given by

$$f = K_{em}K' \left(\frac{\mu}{r^2}\right) (N_1I_1l_1 \sin \theta_1)(N_2I_2l_2 \sin \theta_2)$$

where N_1 and N_2 are the number of turns of the first and second circuit elements, I_1 and I_2 are the currents in the first and second elements, respectively, l_1 and l_2 are the lengths of the first and second conducting elements, and θ_1 and θ_2 are the angles between straight lines connecting the two current-carrying elements and the direction of the first and second elements, respectively. In mks units, f is measured in newtons, I in amperes, l in meters, and μ in henrys per meter. The factor K_{em} relates units of mechanical force with units of current, and K' is a factor, as given in Table 6, whose value depends on whether a rationalized or unrationalized system of units is employed.

125. Relation between Static and Dynamic Force Fields. Coulomb's law for electric charges and magnetic poles provides a means of relating mechanical forces with the magnitudes of electric charges and magnetic poles. On the basis of Coulomb's law for electric charges, the electrostatic system of units has been developed. Quite independently, the magnetic system of units has been derived on the basis of Coulomb's law for magnetic poles. The force between two current-carrying elements provides a means for relating the static and dynamic force fields, since currents produce magnetic effects and are but the flow of charges. It also provides a means for checking and correlating the system of units established for the electrostatic and magnetostatic cases.

Equating the forces obtained from charges, single-turn current-carrying circuit elements, and magnetic poles, the three force expressions are

$$f = K_eK' \frac{Q_1Q_2}{r^2} = K_{em}K' \frac{1}{\mu r^2} (\mu I_1l_1 \sin \theta_1)(\mu I_2l_2 \sin \theta_2) = K_mK' \frac{M_1M_2}{\mu r^2}$$

By the definition of unit current and magnetic shell, the last two expressions must be identical so that $K_{em} = K_m$. To simplify calculations, let $Q_1 = Q_2 = Q$, $M_1 = M_2 = M$, $I_1l_1 = I_2l_2 = Il$, and let $\theta_1 = \theta_2 = \theta = 90°$ so that $\sin\theta = 1$. Then, for r the same in all cases

$$K_e\left(\frac{Q^2}{\epsilon}\right) = K_m\left(\frac{M^2}{\mu}\right) = K_m\mu(Il)^2$$

For a steady current, $I = Q/t$; hence,

$$K_e\left(\frac{Q^2}{\epsilon}\right) = K_m\mu\left(\frac{Ql}{t}\right)^2$$

from which

$$\frac{K_e}{K_m}\frac{1}{\mu\epsilon} = \left(\frac{l}{t}\right)^2 = v^2$$

where the velocity v is given by l/t.

If the permittivity and permeability of free space are both taken as unity, as they are in the cgs electrostatic and electromagnetic (magnetostatic) systems of units, the ratio of units in the two systems has the dimensions of velocity squared. Further examination of the units of measurement in these two systems shows that v is the same as the velocity of light in free space to well within the limits of experimental error. For mediums other than that of free space, the actual values of μ and ϵ must be used to determine the velocity of propagation of electrical effects.

The somewhat unexpected result that the ratio of dimensions in the cgs electrostatic and magnetostatic systems has the dimensions of velocity squared comes from the fact that values for permeability and permittivity were arbitrarily assigned at a time before there was any known relation between electricity and magnetism.

126. Magnetomotive Force. The magnetomotive force acting in any closed path in a magnetic field is the line integral of the magnetizing force around the path. In any closed path, the magnetomotive force resulting from the flow of current through a path is proportional to the current that links its path. In mks units, the magnetomotive force is expressed in ampere-turns, and around any closed path has the value

$$\oint \mathcal{H}\cos\theta\, dl = K'''NI$$

where θ is the angle between the direction of $\mathcal{H}$ and that of l, N is the number of times the path links the magnetic field, I is the current in amperes, and K''' has the value given in Table 6.

127. Ampère's Circuital Law for Magnetic Intensity. In radio practice we are interested not only in conduction currents and circuit phenomena (in which current flows through filamentary circuit paths), but also in the general flow of current through space, more conveniently expressed in terms of current density. Furthermore, the current density may have displacement as well as conduction components. For the case in which current density flows through a surface, Ampère's circuital law of magnetic intensity may be stated as follows: The magnetizing force around a closed loop is equal to the total current flowing through the surface bounded by the loop. Mathematically,

$$\oint \mathcal{H}\cos\theta\, dl = \iint_S K'''\left(\mathcal{I}_c + K''\frac{d\mathfrak{D}}{dt}\right)_n ds = K'''\left(I_c + K''\frac{d\psi}{dt}\right)$$

In this case $\mathcal{I}_c$ is the conduction component of the current density and $d\mathfrak{D}/dt$ is the displacement component, while I_c is the conduction component of the total current and $d\psi/dt$ is the displacement component of current. The subscript, n, designates the normal component. In the mks system of units, current is measured in amperes, current density in amperes per square meter, and magnetic field intensity in ampere-turns per meter.

The integral form of Ampère's circuital law, above, is particularly suitable when the net over-all, or integrated effects of the resultant magnetic field and electric currents are of primary concern, as in dealing with electric circuits. When dealing with radiation phenomena, field concepts, or other matters in which the spatial distribution of electromagnetic effects is important, it is more convenient to deal with the differential form of Ampère's circuital equation in which the directional components of the current density and electric flux density are expressed in terms of the curl or rotational components of the magnetic field intensity.

In deriving the differential form of Ampère's circuital law, the resultant current flow is resolved into three orthogonal components; likewise the resulting magnetic
FIG. 30. Diagram illustrating the integral form of Ampère's circuital law.

field is resolved into three orthogonal components such that the circuitation of the magnetic field is in a plane normal to the direction of flow of the electric current. The resultant effect, at a point in space, is then the vector sum of the three orthogonal components.

In rectangular coordinates the differential expression for Ampère's circuital law takes the form

$$\mathbf{i}K'''\left(\mathcal{J}_x + K''\frac{d\mathfrak{D}_x}{dt}\right) + \mathbf{j}K'''\left(\mathcal{J}_y + K''\frac{d\mathfrak{D}_y}{dt}\right) + \mathbf{k}K'''\left(\mathcal{J}_z + K''\frac{d\mathfrak{D}_z}{dt}\right)$$
$$= \mathbf{i}\left(\frac{\partial\mathcal{H}_z}{\partial y} - \frac{\partial\mathcal{H}_y}{\partial z}\right) + \mathbf{j}\left(\frac{\partial\mathcal{H}_x}{\partial z} - \frac{\partial\mathcal{H}_z}{\partial x}\right) + \mathbf{k}\left(\frac{\partial\mathcal{H}_y}{\partial x} - \frac{\partial\mathcal{H}_x}{\partial y}\right)$$

The sum of the three directional components gives the relation, at a point, for Ampère's circuital law.

The diagram of Fig. 30 represents the relation existing between the direction of the flow of current, the direction of the magnetic field intensity, and the direction of a closed path, as called for by Ampère's circuital law.

128. Electromotive Force. Electromotive force (emf) is that property of a physical device which tends to produce an electric current in a circuit. It is also that property of a system which tends to alter the motion of electricity, or to maintain its motion

against resistance. *Like the difference of potential, emf is measured by the energy per unit charge imparted to the charge as it travels through a region in which the emf acts. It is evident, therefore, that the emf is not, as its name would imply, a force, but rather work per unit charge.* In the mks system of units, the unit of emf is the joule per coulomb, to which the name "volt" has been given.

One form of emf has already been encountered, that of electrostatic potential difference, which exists by virtue of the position of electric charges. Sources of electric energy, such as batteries, thermocouples, and photoelectric devices, are capable of producing an emf by chemical action or by the action of radiant energy. Another type of emf, first discovered by Faraday, results from the motion of a conductor in a magnetic field; it is called the "induced" emf, or the "electromotive force of induction."

129. Faraday's Circuital Law for Induced Emf. As a result of extensive researches, Faraday, in 1833, was able to announce his discovery of the relation governing an emf appearing across a section of a conductor having motion relative to a magnetic field in which it is situated. In the following year, Lenz clearly specified the relationships between the directions of the magnetic field, the motion of the conductor relative to the magnetic field, and the polarity or direction of the resulting emf. As amplified by Lenz, Faraday's law may be stated as follows: When the change in magnetic flux linkages is caused by the relative motion of a magnetic field and a conductor forming part of an electric circuit, an electromotive force is induced in the circuit, the magnitude of which is equal to the time rate of decrease of the flux linkages.

A flux linkage is defined as the interlinking of a line of magnetic flux with a single conductor, and is represented by the symbol Λ. Therefore, $\Lambda = N\phi$ flux linkages signifies the product of ϕ lines of magnetic flux linking N turns of a conductor or, conversely, N conductors linking the average value of the magnetic flux, ϕ. With this notation, the magnitude and direction of the emf induced in a conductor is given by

$$E = -\frac{d\Lambda}{dt} = -\frac{d(N\phi)}{dt}$$

where, in mks units, E is the induced emf in volts, N is the number of conductors (or number of turns of a single conductor closely bunched together), and ϕ is the average value of the magnetic flux in webers.

The relation given above is quite suitable for electric circuits but, when dealing with field phenomena, the equations are more convenient when expressed in terms of the electric field intensity and the magnetic flux density together with elements of length and surface. Since the drop in emf around a closed loop is given by the relation $\oint \mathcal{E} \cos \theta \, dl$ and the magnetic flux traversing the surface enclosed by the loop is given by $\iint_s \mathcal{B} \cos \theta' \, ds$, Faraday's law for electromotive induction may be written as

$$\oint \mathcal{E} \cos \theta \, dl = -\frac{\partial}{\partial t} \iint_s \mathcal{B} \cos \theta' \, ds$$

where (in mks units) $\mathcal{E}$ is the electric field intensity given in volts per meter, $\mathcal{B}$ is the magnetic flux density in webers per square meter, dl is an element of length in meters, ds is an element of area in square meters, and θ is the angle between the direction of the electric field intensity and the line element, whereas θ' is the angle between the direction of the magnetic flux density and the normal to the surface through which the flux passes.

The magnetic flux density is a continuous function of time, t, and surface, s. For such conditions it is permissible to perform the differentiation under the integral sign[1] so that Faraday's circuital law may also be written in the form

$$\oint \mathcal{E} \cos \theta \, dl = -\iint_s \frac{\partial(\mathcal{B} \cos \theta')}{\partial t} \, ds$$

where the symbolic notation is the same as before.

[1] Sokolnikoff, I. S., and E. S. Sokolnikoff, "Higher Mathematics for Engineers and Physicists," McGraw-Hill, 1941.

At a point, this field relation may be expressed in the differential form

$$\mathbf{i}\left(\frac{\partial \mathcal{E}_z}{\partial y} - \frac{\partial \mathcal{E}_y}{\partial z}\right) + \mathbf{j}\left(\frac{\partial \mathcal{E}_x}{\partial z} - \frac{\partial \mathcal{E}_z}{\partial x}\right) + \mathbf{k}\left(\frac{\partial \mathcal{E}_y}{\partial x} - \frac{\partial \mathcal{E}_x}{\partial y}\right) = -\left(\mathbf{i}\frac{\partial \mathcal{B}_x}{\partial t} + \mathbf{j}\frac{\partial \mathcal{B}_y}{\partial t} + \mathbf{k}\frac{\partial \mathcal{B}_z}{\partial t}\right)$$

where, in mks units, $\mathcal{E}$ is the electric field intensity in volts per meter, $\mathcal{B}$ is the magnetic flux density in webers per square meter, and the directional components are indicated, in rectangular coordinates, by the subscripts.

In the diagram of Fig. 31 is represented flux density, $\mathcal{B}$, flowing through the surface, s, enclosed by a looped conductor. The direction between the plane of the closed conductor and the plane normal to that of the magnetic flux is θ, and the direction or polarity of the emf induced in the loop is also indicated.
FIG. 31. Representation of integral form of Faraday's circuital law for induced emf.

130. Potential Difference, Electromotive Force, and Voltage. The terms "potential difference," "electromotive force," and "voltage" are often used loosely and indiscriminately, although there is a clear distinction between the first two of these at least.

Strictly speaking, the potential difference is the difference in electrostatic potential due to the distribution of electric charges, and the magnitude of the potential difference depends upon the magnitudes and positions of the charges. The concept is also extended, however, to the case of moving charges, *i.e.*, the case in which current flows, in which case the potential difference is interpreted, at any instant of time, to be the same as the electrostatic potential difference for the charge configuration at the instant in question. This extension of the concept of electrostatic potential difference is valid for time variations of the charges, or frequencies of current, so long as the electromagnetic field is essentially of equal magnitude, at any instant of time, for the entire region occupied by the electrical system with which it is associated. At sufficiently high frequencies, the concept is no longer applicable.

An electric field may be produced by the distribution of electric charges or, in accordance with Faraday's circuital law, it may be produced by the relative motion of a conductor and a magnetic field.

The term "voltage" is used to designate potential difference whether due to the simple or extended concepts of electrostatic potential or due to induced emf.

It is worth noting that currents are not necessarily induced. If emf is induced in a closed circuit, a conduction current will flow, but the emf will be induced whether the circuit is open or not. Conduction current cannot flow in an open circuit, however.

THE ELECTROMAGNETIC FIELD

131. Electromagnetic Field Relations. As concerns its electrical aspects, the basis of radio communication resides in the four electromagnetic field relations known as Maxwell's equations, which have already been developed and are summarized in Table 8. They are fundamental in the sense that from them can be derived relations of circuit behavior, the wave equation, the propagation characteristics of electromagnetic waves (if enough is known of the transmission medium), and the like.

Maxwell's electromagnetic field equations should be regarded as a compact and generalized means of expressing known electrical phenomena. This set of relationships differs from most equations used by engineers in that they do not provide information in a form that is directly applicable for design purposes. In fact, the use of these equations for most problems of engineering application usually involves such difficulties of specifying boundary conditions and mathematical manipulation that the Maxwell equations have little direct usefulness to engineers. But by no means do these limitations invalidate their utility, for this set of relations can be made to yield other relationships (*e.g.*, the laws for electric circuits) applicable in special cases and sufficiently easy to manipulate as to be of great practical utility.

In Table 8 each of the four Maxwell equations specifying a fundamental electromagnetic relation is interpreted in six different ways in addition to the pictorial representation referred to by the figure numbers. The first column gives the usual name of the relationship. The second column provides a word statement of each relation, which aims to express the fundamental physical behavior without recourse to mathematical notation. The third column gives the figure number in which the approximate physical relations are pictorialized. The next columns express the result of physical observations in the classical form of integral equations which take account of the total, net, or resultant of all directional components of the field. The last columns are the equivalent integral expression in the notation of vector analysis. The integral form is the basis of circuit equations and is most suitable where the integrated electric and magnetic fields are most conveniently expressed in terms of voltage and current. Each of the field components is also expressed in the form of a differential equation, one column giving the classical form (in rectangular coordinates only) and the other giving the equivalent in vector notation. As given in Table 8, the equations are suitable for either the rationalized or unrationalized system. The differential form of the field equations is most suitable for the determination of rela-

Table 8. Alternative Statements of Maxwell's Equations

Name	Statement	Fig.	Classical form		Vector form	
			Integral	Differential (point rel.)	Integral	Differential (point rel.)
1. Gauss's theorem for electric flux density (Coulomb's law for single dielectric)	The electric flux diverging from a closed surface, ψ, is equal to K times the total density enclosed by the surface or to K times the charges enclosed by the surface enclosing the volume	28	$\psi = \oiint_s \mathcal{D} \cos \theta' \, ds = \iiint_r \rho \, dr = K'''Q$	$\frac{\partial \mathcal{D}_x}{\partial x} + \frac{\partial \mathcal{D}_y}{\partial y} + \frac{\partial \mathcal{D}_z}{\partial z} = \begin{cases} K'''\rho \\ \text{or} \\ 0 \end{cases}$	$\psi = \oiint_s \mathcal{D} \cdot n \, ds$	$\text{div}\, \mathcal{D} \equiv \nabla \cdot \mathcal{D} = \begin{cases} K'''\rho \\ \text{or} \\ 0 \end{cases}$
2. Gauss's theorem for magnetic flux density (Coulomb's law for a single magnetic medium, or law of magnetic flux density)	The magnetic flux diverging from a closed surface, ϕ, is zero. It follows that magnetic lines of force are continuous, or form closed loops	29	$\phi = \oiint_s \mathcal{B} \cos \theta' \, ds = 0$	$\frac{\partial \mathcal{B}_x}{\partial x} + \frac{\partial \mathcal{B}_y}{\partial y} + \frac{\partial \mathcal{B}_z}{\partial z} = 0$	$\phi = \oiint_s \mathcal{B} \cdot ds$	$\text{div}\, \mathcal{B} \equiv \nabla \cdot \mathcal{B} = 0$
3. Circuital law for magnetic intensity (from Ampere and Maxwell)	The magnetomotive force around a closed loop, $\mathfrak{F}$, is proportional to the total current flowing through the surface bounded by the loop	30	$\mathfrak{F} = \oint \mathcal{H} \cos \theta \, dl = \iint_s K''' \left(\mathcal{J}_c + K' \frac{\partial \mathcal{D}}{\partial t} \right)_n ds$	$\frac{\partial \mathcal{H}_z}{\partial y} - \frac{\partial \mathcal{H}_y}{\partial z} = K''' \left(\mathcal{J}_x + K'' \frac{\partial \mathcal{D}_x}{\partial t} \right)$ $\frac{\partial \mathcal{H}_x}{\partial z} - \frac{\partial \mathcal{H}_z}{\partial x} = K''' \left(\mathcal{J}_y + K'' \frac{\partial \mathcal{D}_y}{\partial t} \right)$ $\frac{\partial \mathcal{H}_y}{\partial x} - \frac{\partial \mathcal{H}_x}{\partial y} = K''' \left(\mathcal{J}_z + K'' \frac{\partial \mathcal{D}_z}{\partial t} \right)$	$\mathfrak{F} = \oint \mathcal{H} \cdot dl = \iint_s K''' \left(\mathcal{J}_c + K'' \frac{\partial \mathcal{D}}{\partial t} \right) \cdot ds$	$\text{curl}\, \mathcal{H} \equiv \nabla \times \mathcal{H} = K''' \left(\mathcal{J}_c + K'' \frac{\partial \mathcal{D}}{\partial t} \right)$
4. Circuital law for induced emf (generalized law of Faraday)	In all cases in which the flux linkages change, the algebraic value of induced emf in a closed loop, E, is equal to the time rate of decrease of flux linkages enclosed by the loop	31	$E = \oint \mathcal{E} \cos \theta \, dl = -\frac{\partial}{\partial t} \iint_s \mathcal{B} \cos \theta' \, ds = -\iint_s \frac{\partial(\mathcal{B} \cos \theta')}{\partial t} ds$	$\frac{\partial \mathcal{E}_z}{\partial y} - \frac{\partial \mathcal{E}_y}{\partial z} = -\frac{\partial \mathcal{B}_x}{\partial t}$ $\frac{\partial \mathcal{E}_x}{\partial z} - \frac{\partial \mathcal{E}_z}{\partial x} = -\frac{\partial \mathcal{B}_y}{\partial t}$ $\frac{\partial \mathcal{E}_y}{\partial x} - \frac{\partial \mathcal{E}_x}{\partial y} = -\frac{\partial \mathcal{B}_z}{\partial t}$	$E = \oint \mathcal{E} \cdot dl = -\frac{\partial}{\partial t} \iint_s \mathcal{B} \cdot ds = -\iint_s \frac{\partial \mathcal{B}}{\partial t} \cdot ds$	$\text{curl}\, \mathcal{E} \equiv \nabla \times \mathcal{H} = -\frac{\partial \mathcal{B}}{\partial t}$

tions at a point, or where it is necessary to take into account the spatial and directional distributions of the electric and magnetic effects of electromagnetic phenomena. The classical method of writing these equations is somewhat long but, for purposes of physical interpretation, has the advantage of illustrating the manner in which each directional component of the electromagnetic field is separately involved. The vector form is much more compact and has the advantage that the same compact notation is used for any orthogonal system of coordinates. A working knowledge of vector analysis is required before the physical interpretation of the equations is evident, however.

132. Maxwell's Equations for Special Cases. Maxwell's equations may be grouped into five distinct divisions, depending upon whether or not certain effects are functions of time and whether the magnitude of certain physical effects is sufficiently small to be negligible. From an engineering point of view, the separate cases are (1) the static case, (2) the steady case for stationary electric and magnetic fields, (3) the quasi-steady case for closed circuits in which, except for capacitors, the displacement component of the current is sufficiently small to be negligible, (4) the quasi-steady case for open circuits in which displacement current is no longer negligible, and (5) the general case of dynamic phenomena in which the magnitude of the displacement current is appreciable and may exceed that of conduction current. These cases are discussed below.

1. *The Static Case.* The static case is that, encountered in electrostatics and magnetostatics, for which no time variations of electric charges or magnetic poles occur. There is no flow of charge and, therefore, there can be neither conduction nor displacement currents. Except for Gauss's theorem for electric charges, the right-hand side of all the Maxwell equations reduces to zero; it may even reduce to zero for Gauss's theorem for electric charge if the medium is charge-free. The electrostatic and magnetostatic fields have independent laws (the divergence equations deduced from Coulomb's law) even though the mathematical forms of these laws are similar. Energy is associated with the electrostatic field and also, separately, with the magnetostatic field. The electrostatic and magnetostatic fields become superimposed upon one another without influencing each other in the slightest degree; hence, the complete segregation of the two kinds of fields and the impossibility of determining the connection between electricity and magnetism for the static case.

Although the static case has been important in the development of the classical theory of electricity, it can obviously have no direct application in conveying electrical communication, for the essence of electrical communication is the time variation of some electrical quantity in accordance with the information to be transmitted.

2. *Steady Case for Stationary Electromagnetic Field.* The steady case is that, encountered in d-c circuits and systems, for which there is a constant and steady flow of electric charges to produce a conduction (or convection) current, but no displacement current is possible. All of Maxwell's equations may be applied here except that expressing Faraday's circuital law of induced emf which, of course, depends upon a time-varying magnetic field. Electric and magnetic effects are now no longer independent of one another. The electric field in a conductor establishes a streamline of flow of electric charges which, in turn, gives rise to a magnetic field that is constant with respect to time and does not react to modify the electric field. A continual transformation of electric energy into heat takes place. Lumped constant circuit elements can be rigorously defined for this case; in fact, it is the only case for which the circuit parameters are rigorously defined. Yet, in the true steady case, *i.e.*, free from transients, only the resistance parameter is encountered in circuit behavior; inductance and capacitance determine circuit behavior only for transient conditions.

The steady case—the d-c or stationary electromagnetic field case—has no direct active role in electrical communication that requires time variations of some electrical quantity. Nevertheless, the steady case is of considerable indirect interest to engineers because certain important concepts (*e.g.*, lumped circuit parameters) are rigorously defined only for this case. Moreover, steady voltages and currents are often

required in order that certain pieces of radio equipment (*e.g.*, electron tubes) may operate properly in their communication application.

3. *Quasi-steady Case for Closed Circuits.* This is probably the best known of the five cases since it is the most frequently encountered in electrical engineering. For this case the conduction current density, the magnetic flux linkages, and the induced emf are all single-valued functions of time and (except in capacitors) the displacement current, although not zero, is negligible compared to the conduction (or convection) component and hence may be ignored or neglected. For this case consideration is restricted to electrical processes occurring so slowly that, at any instant of time, the entire electromagnetic field surrounding the electrical system may be regarded as uniform. The electric and magnetic effects for this case are mutually related to the extent that a varying current produces a varying magnetic field which is capable of inducing a varying emf in a neighboring conductor which establishes a varying current if the conductor is closed. The fact that the displacement current is negligible precludes the possibility of radiation, or the mutual self-sustenance of electric and magnetic field intensities in dielectrics. All Maxwell equations have interpretation, but (except in capacitors) displacement currents are negligibly small and, therefore, are omitted from consideration. At any instant of time the current at all points in a (series) circuit is the same. The magnitude of the displacement current in capacitors is equal to the magnitude of the conduction current in a series circuit. A very convenient and highly useful simplification of Maxwell's equation results from neglecting the displacement current.

The very great advantage obtained for this case is that the number of variables determining the state of the electromagnetic field is greatly reduced. In fact, for most problems in this case, it is possible to omit consideration of space variables and deal only with time variations of the voltage and current—the integrated effects of the electric and magnetic field components. In the case of linear conductors the analysis can be still further simplified, for the current is determined by the voltage; hence, the entire phenomena may be expressed in terms of a single varying time function—either the current or the voltage. Usually the applied voltage is known, and if the current is then determined as a function of time, the problem of electrical behavior for this case is considered to be solved.

As in the steady case, the electric field intensity establishes a streamline of flow (tangential along the conductors) of electric charges of varying magnitude producing a varying magnetic field about the conductor.

For this case, lumped circuit parameters are no longer rigorously defined because displacement current is not taken into account. Therefore, the use of lumped circuit parameters leads to approximate rather than exact solutions of the electric circuit behavior. The errors involved in such approximations are often sufficiently small to be completely negligible for engineering (and even for a good deal of scientific) work. The magnitude of the displacement current relative to that of the conduction current—and, hence, the error due to circuit analysis based on steady-case derivations—increases with frequency. Such error becomes appreciable (usually for frequencies above 50 to 100 Mc) for those cases in which the dimensions of the electrical system are comparable to a wavelength of oscillation or (what is the same thing) for those cases for which the instantaneous electromagnetic field can no longer be regarded as uniform throughout the space occupied by the electrical system. Distributed circuit parameters, *i.e.*, those circuit parameters whose properties are spatially distributed throughout the region of the electrical system instead of being considered as lumped at a point in space, may often be used in place of lumped circuit parameters to obtain solutions of electric circuits (such as transmission lines) in which at least one dimension is an appreciable portion of a wavelength or more.

4. *Quasi-steady Case for Open Circuits.* This case is identical to that above with the following exceptions: Because displacement currents are no longer of negligible magnitude, the current at all points of an open circuit is no longer the same as in the case for closed circuits. The flow of energy is no longer tangential along conductors

but has a perpendicular component as well. The electric energy of the field may no longer be neglected in comparison with the magnetic energy, and the magnetic energy can no longer be expressed accurately by conditions that apply for stationary currents. Radiation phenomena begin to become important, for energy may leave the open circuit and be propagated into space. These conditions are a result of the fact that the displacement current can no longer be regarded as negligible, although for this case it is not yet regarded as exceeding the magnitude of the conduction current.

5. *General Case for Dynamic Phenomena.* For this case, no restrictions are placed on Maxwell's equations. It is usually exceedingly difficult to apply the general equations to engineering problems, and this practical difficulty impedes the application of the general equations. For this case, the displacement current has appreciable magnitude. All four Maxwell equations (and all terms in each equation) are significant and must be used in their complete form. Circuit concepts are, generally, no longer valid. For this case, the electromagnetic field can no longer be regarded as uniform throughout the spatial distribution of the electrical system at any instant of time. Consequently the general case must be employed when very high frequencies are encountered or when the dimensions of the electrical system are comparable to a wavelength of oscillation.

Because displacement currents are appreciable, there is a mutual and self-sustained reaction between the electric and magnetic components of the electromagnetic field that leads to the phenomena of radiation.

133. Circuit and Field Phenomena. For convenience in radio engineering practice, Maxwell's equations may be divided into two broad categories in which the quasi-steady case for closed circuits and the general case are the most frequently employed.

Table 9. Comparison of Electromagnetic Field and Electric Circuit Concepts*

Electromagnetic Field Concept	Electric Circuit Concept
Electric field intensity at a point in the medium	Electric voltage in branches of an electric circuit
Magnetic field intensity at a point in the medium	Electric current flowing through an electric circuit branch
Resistivity, or resistance per unit cube, of the medium	Resistance in a branch of the circuit
Permeability of the medium	Inductance of a branch of the circuit
Permittivity of the medium	Capacitance of a branch of the circuit
Energy stored in the electric field for unit volume of the medium	Energy stored in the dielectric of a capacitor
Energy stored in the magnetic field for unit volume of the medium	Energy stored in the magnetic field about an inductor
Energy dissipated in unit volume of the medium	Energy dissipated as heat in a conductor or resistor

* This table is a slight modification of that appearing in J. G. Brainerd, G. Koehler, H. J. Reich, and L. F. Woodruff, "Ultra-high-frequency Techniques," p. 371, Van Nostrand, 1942.

Upon the first of these cases is built the highly convenient theory using lumped circuit parameters, which are usually but not necessarily considered to be linear. The electromagnetic wave theory (including radiation phenomena and the behavior of electrical systems at very high frequencies) must necessarily be built upon the more general case of Maxwell's equations. The points of view in these two cases differ appreciably, as does also the emphasis with respect to spatial considerations. The approximately analogous concepts for these two cases are given in Table 9, which is intended to draw attention to the change in emphasis required for the two cases rather than to establish rigorous parallelisms.

The relations between circuit and electromagnetic field theory have been ably stated by Carson[1] in the following words:

> The equations of electric circuit theory in their present form are essentially a generalization of the observations of Ohm, Faraday, Henry, Kirchhoff, and others, and their development preceded the electromagnetic theory of Maxwell and Lorentz. Naturally, in view

[1] Carson, John R., Electromagnetic Theory and the Foundations of Electric Circuit Theory, *Bell System Tech. J.*, **6** (1), 1, January, 1927.

of its early development, circuit theory embodies approximations, the precision of which cannot be determined from the observations on which it is based. For example, circuit theory explicitly ignores the finite velocity of propagation of electromagnetic disturbances, and hence the phenomena of radiation. Again it involves the assumption that the network can be represented by a finite number of coordinates and, thus, that it constitutes a rigid dynamic system. The rigorous equations of electromagnetic theory formulate the relations between current and charge densities and the accompanying fields. Circuit theory, on the other hand, expresses approximate relations between total currents and impressed electromotive forces.

ELECTRIC CIRCUITS

134. Electric Circuit Concepts. An electric circuit is a path or a group of interconnected paths capable of carrying conduction electric currents. A closed electric circuit is a continuous path in the form of a loop or group of interconnected loops in which each loop is capable of carrying an electric current.

An assembly of lumped circuit elements is an electric circuit in which dissipation of energy and the storage of electric and magnetic energy may be considered as concentrated separately in each of three different circuit elements of physically small size. The physical size of lumped circuit elements is sufficiently small (theoretically infinitesimal) that, at any instant of time and over the region of space occupied by the circuit, the electric and magnetic fields are uniform. This condition is rigorously true for the steady (d-c) case and very nearly true if time variations of the electric and magnetic field are sufficiently slow. A circuit element is a physical device (usually with two terminals) exhibiting the electrical property of (1) energy dissipation or conversion of electrical energy into heat in a resistor, (2) storage of electric energy in a capacitor (or condenser), or (3) storage of magnetic energy in an inductor, or coil. These three circuit elements dissipate or store energy, and a drop of potential difference exists across them when an electric current flows through them. A fourth kind of circuit element, called a "source" of electric energy, transforms chemical, mechanical, or other energy into electric energy and has a rise of potential across its terminals.

A linear circuit is an electric circuit in which a linear differential equation precisely expresses the relations between the magnitudes of the instantaneous current and those

of the rises and drops of potential difference across the circuit elements. A linear circuit is composed of circuit elements whose parameters (*i.e.*, properties for storing or dissipating energy) are independent of the magnitude of the voltage across, or the current through, the elements. Those circuit elements whose properties are dependent upon the voltage or current are termed "nonlinear" circuit elements.

Lumped or concentrated circuit elements provide a convenient means for dealing with the integrated effects of electrical phenomena since (except in the case of capacitors in which electric energy is stored) only conduction current is important. The magnitude of the displacement current in capacitors is equal to the conduction current in the leads to the capacitor; hence, circuit phenomena are completely expressible in terms of the conduction current.

In developing the concepts of lumped circuit elements, all electrical effects, including the electric and magnetic fields, taking place are limited to the immediate vicinity of the electrical system or circuit. A source of electric energy (rise of potential difference) establishes electric field intensity along the physical configuration of the circuit elements, and all currents flow along the circuit conductors as a streamline, in the same direction as that of the electric field intensity, or the drop in potential difference.[1] The geometric configuration of the circuit, therefore, determines the space geometry of the system. Accordingly, it is possible to dispense with considerations of space coordinates in lumped circuit phenomena and consider only the time variations of the integrated electric field intensity and current density, *i.e.*, the time variations of the potential differences and the current. The concept of lumped circuit elements permits the solution—even if only approximate—of many problems that are beyond our present ability to solve by means of the more rigorous method employing electromagnetic field relations.

Strictly speaking, lumped circuit concepts apply only to the case in which the electric field intensity and current density are invariant with time, *i.e.*, to the steady electromagnetic field or the d-c case. As a practical matter, with suitable modifications or extensions, the steady-case concepts are applicable to those cases in which time variations of $\mathcal{E}$ and $\mathcal{J}$ (or E and I) are present, provided the dimensions of the circuit are sufficiently small so that, at any instant of time, the electric and magnetic fields are essentially uniform throughout the region occupied by the circuit and provided that (except in capacitors) displacement currents are negligible and, therefore, radiation is inappreciable.

The idea of lumped circuit elements applies to conducting circuits composed of filamentary conductors through which the current flows and along which there are differences of potential or of electric field intensity. An exception to this statement must be made for capacitors, for the capacitance parameter necessarily involves a volume, across opposite faces of which exists a difference of potential.

Circuit phenomena deal with the integrated effects of $\mathcal{E}$ and $\mathcal{J}$; hence, these two quantities may be replaced by potential difference (E) and current (I), respectively. In developing the concept of lumped circuit constants, use is made of the relations

$$\mathcal{B} = \mu\mathcal{H} \qquad \mathcal{J} = \sigma\mathcal{E}$$
$$\mathcal{D} = \epsilon\mathcal{E} \qquad \mathcal{E} = \rho\mathcal{J}$$

where μ, ϵ, σ, and ρ may vary with temperature but, for linear circuit elements, are invariant with respect to potential differences across, or current through, the circuit element. In practice this restriction does not impose objectionable limitations, except that analyses based on the assumption of constant permeability imply that corrections or modifications of the linear circuit theory are required in dealing with circuit elements employing ferromagnetic materials. The principle of superposition (Sec. 146) applies only to systems composed of linear circuit elements.

Three conditions exist for formulating the circuit parameters of lumped circuit elements. In each case the property of storing or dissipating electrical energy is

[1] This statement applies to the conventional direction of the current; the electron flow is opposite to that stated here.

represented by a different circuit element. In conductors the electric fields are accompanied by pure conduction currents and the dissipation of electrical energy in the form of heat. These are characteristic properties of resistors. The electric fields in dielectrics are accompanied by displacement currents and the storage of electrical (potential) energy within the dielectric. This is a characteristic property of capacitors. Magnetic fields are associated with the conduction of currents and are accompanied by the storage of magnetic (kinetic) energy. This is a characteristic property of inductors.

The circuit properties of resistance, capacitance, and inductance as employed in electrical analysis are idealized concepts. As such they represent hypothetical and limiting cases that can be approached but never fully attained in the actual embodiment of mathematical ideas as physical pieces of equipment. No physical circuit element embodies purely and completely only that circuit property for which it is named. All embody more or less perfectly that circuit property for which they are named, but they also embody the remaining two circuit properties. In well-designed circuit elements the extent to which the element conforms to the mathematical ideal circuit property is a matter of design and application of the element. The extraneous circuit properties can usually be made so small as to be of minor importance, except where the frequency of variation of the voltage and current is high. In any case, the actual behavior of any physical circuit element can be represented to any desired degree of approximation or precision by suitable combinations of idealized circuit parameters.

The idealized circuit properties discussed in the following sections are those rigorously defined for the steady case. This conventional point of view fails to take in account certain matters, such as the depth of penetration and phase differences, which become important at very high frequencies and require modifications of the treatment given here for extension to high frequencies. For treatment of these more advanced topics, the reader is referred to other chapters of this handbook or to references giving more specialized treatments of this topic.[1]

135. Resistance and Conductance. Resistance is the (scalar) property of an electric circuit, or of any body that may be used as a part of an electric circuit, which determines for a given current the rate at which electric energy is converted into heat or radiant energy and which has a value such that the product of the resistance and the square of the current gives the rate of energy conversion. In the general case, resistance is a function of the current, but the term is most commonly used in connection with circuits in which the resistance is independent of the current.

Conductance is the property of an electric circuit, or of a body that may be used as a part of an electric circuit, which determines, for a given emf in the circuit or for a given potential difference between the terminals of a part of a circuit, the rate at which electric energy is converted into heat or radiant energy, and which has a value such that the product of the conductance and the square of the emf, or potential difference, gives the rate of energy conversion. In the general case, conductance is a function of the potential difference, but the term is most often used in connection with circuits in which the conductance is independent of the potential difference.

If an electric field is applied to the ends of a conductor of uniform cross section made of homogeneous material, a potential difference will exist across the conductor and a current will flow through it, the charges (electrons) flowing along the streamline of the electric field ($\theta = 0$), since they are assumed not to flow through the dielectric that surrounds the conductor. For the steady case, the current flow will be of uniform current density over each part of the cross-sectional area,[2] so that if s is the area normal to the direction of the conductor, $\mathcal{J} = I/s$. If ρ is the resistivity of the homogeneous material of which the conductor is composed so that $\mathcal{E} = \rho\mathcal{J}$, the potential

[1] These topics are treated in such works as G. P. Harnwell, "Principles of Electricity and Electromagnetism," McGraw-Hill, 1938; A. Hund, "Phenomena in High-frequency Systems," McGraw-Hill, 1936; L. Page, "Principles of Electricity," Van Nostrand, 1931; S. Ramo and J. R. Whinnery, "Fields and Waves in Modern Radio," Wiley, 1944.

[2] This condition is not fulfilled for high frequencies.

difference between points A and B of the filamentary conductor may be expressed as

$$E_{AB} = \int_B^A \mathcal{E} \cos \theta \, dl = \int_B^A \rho \mathcal{J} \cos \theta \, dl = \int_B^A \rho \frac{I}{s} \cos \theta \, dl$$
$$= \int_B^A \rho \frac{I}{s} dl = \rho \frac{l_{AB} I}{s} = RI$$

where $\theta = 0$, and $R = \rho l/s$ is the resistance of the conductor of area s between the points A and B. From a physical point of view, the resistance of a conductor may be regarded as the opposition to the flow of the conduction current through a conductor of specified cross-sectional area, specified resistivity, and specified length. The resistivity, on the other hand, is an inherent property of the material of which the resistor is made and is in no way related to the dimensions of the conductor or resistor.

The resistance of a conductor of uniform cross section and made of homogeneous material may be expressed in terms of the electric field intensity and the current density, or in terms of their integrated effects, voltage, and current, or, alternatively, in terms of the conductor dimensions and resistivity of the material of which the resistor is made. From the foregoing results we have the relation

$$R = \frac{E}{I} = \frac{\int \mathcal{E} \cos (\mathcal{E}, l) \, dl}{\int \cos (\mathcal{J}, n) \, ds} = \frac{\int \mathcal{E} \cdot dl}{\int \sigma \mathcal{E} \cdot ds} = \frac{\mathcal{E} \int dl}{\sigma \mathcal{E} \int ds} = \frac{l}{\sigma s} = \rho \frac{l}{s}$$

where $\int \mathcal{E} \cdot dl$ and $\int \mathcal{J} \cdot ds$ are the field equations for the steady-state-case electric field intensity and current density, respectively. Although the resistance has been specified in terms of the rather special case of a conductor of uniform cross section composed of homogeneous material, this procedure is largely a matter of convenience; the ratio of the two field equations specifies the resistance for any material of whatever physical form the resistor may take.

In the derivation of the constant resistance (above), it was assumed that the material was homogeneous and, therefore, that the resistivity and conductivity were constant. For many materials, these characteristic properties of material are not constant but depend upon the current through, or the potential difference across, the conductor. For such cases, E and I are not linearly related, since the resistance has a unique value for different magnitudes of voltage across or current through it. Since the resistance is no longer constant, it is customary to define the nonlinear resistance as the limiting ratio of the voltage increment to the resulting current increment, as the latter approaches zero. The variational or differential resistance thus defined is usually designated by the letter r and is given mathematically by the relation

$$r = \lim_{\Delta I \to 0} \frac{\Delta E}{\Delta I}$$

where the voltage increment across the resistance is ΔE and the corresponding current increment is ΔI.

The reciprocals of the ohmic resistance, R, and of the variational resistance, r, are sometimes more useful electrical quantities than R and r for circuit calculations. These reciprocal quantities are called the conductance (designated by $G = 1/R$) and the "variational conductance" ($g = 1/r$) and are defined by the equations

$$G = \frac{I}{E} = \frac{\int \int \mathcal{J} \cos (\mathcal{J}, n) \, ds}{\int \mathcal{E} \cos (\mathcal{E}, l) \, dl} = \frac{\mathcal{J} \int \int ds}{\rho \mathcal{J} \int dl} = \frac{s}{\rho l} = \frac{1}{R}$$

for linear conductors, or

$$g = \lim_{\Delta E \to 0} \frac{\Delta I}{\Delta E}$$

for nonlinear conductors.

Resistance is measured in volts per ampere or in ohms in the mks system, and conductance is measured in reciprocal ohms or in mhos.

The linear resistance and linear conductance express an electrical characteristic of those materials or devices obeying Ohm's law. This includes most good conductors encountered in radio practice, particularly those of metals. It does not include conductors composed of carbon, nonhomogeneous materials, or those operating over an appreciable temperature range. Ohm's law does not usually apply for semiconductors. The variational resistance is commonly employed in such nonlinear devices as electron tubes, electric arcs, copper oxide, selenium, or other rectifiers, thyrite nonlinear conductors, and temperature-sensitive conductors. The resistivity of materials commonly employed in the construction of resistors for radio purposes is given in Table 7, Sec. 120.

136. Capacitance and Elastance. Capacitance is that property of a system of conductors and dielectrics which permits the storage of electricity when a potential difference exists between the conductors. The magnitude of the capacitance is

Table 10. Relative Permittivity and Breakdown Voltage of Typical Dielectrics Used in Radio Engineering

Material	Relative permittivity	Breakdown voltage, kv/cm
Ebonite	2.80	300–1,100
Glass	5.4–9.9	300 1,500
Gutta-percha	3.3–4.9	80–200
Mica	5.6–5.8	1,500–2,000
Paraffin	2.20	350
Porcelain	5.73	
Quartz, fused	3.9	
Rubber	......	150–500
Sulfur (amorphous)	3.9	
Wood	4.2–7.8	

expressed as the ratio of the quantity of electricity on the conducting elements to the potential difference between them. If Q is the charge stored and E is the difference of potential between the conductors, the capacitance is defined to be

$$C = \frac{Q}{E}$$

If there are two conductors in a homogeneous, isotropic medium between which an electric field intensity, $\mathcal{E}$, produces a difference of potential $E = \int \mathcal{E} \cos \theta \, dl$ and if the electric flux between the two conductors is $\psi = \iint \mathfrak{D} \cos \theta' \, ds$ so that the charge on the conductor is $Q = K'\psi$, the capacitance is defined to be

$$C = \frac{Q}{E} = \frac{K'\psi}{E} = \frac{K' \iint_s \mathfrak{D} \cos \theta' \, ds}{\int \mathcal{E} \cos \theta \, dl} = \frac{K'\epsilon\mathcal{E} \iint_s ds}{\mathcal{E} \int dl} = K' \frac{\epsilon s}{l}$$

where ϵ is the permittivity of the dielectric material, s is the surface area of the conducting plates bounding the dielectric, and l is the distance between the conducting surfaces. It is interesting to observe that this expression shows the physical dimensional factors upon which the capacitance is based. The permittivity and breakdown voltage of some representative dielectrics are given in Table 10.

The expression above gives the capacitance as defined for static conditions since it has been derived on the assumptions that $\mathfrak{D}$ and $\mathcal{E}$ were time-invariant. Exactly the same expressions are obtained if $\mathfrak{D}$ and $\mathcal{E}$ are functions of time, but in this case the equation obtained for capacitance may now be expressed for the dynamic cases in

terms of varying values of potential difference and displacement current. For the dynamic case the expression for capacitance becomes

$$C = \frac{[d(K'\psi)/dt]}{dE/dt} = \frac{K'(d\psi/dt)}{dE/dt} = \frac{K' \iint_s (d\mathfrak{D}/dt)\, ds}{dE/dt} = \frac{I_d}{dE/dt} = I_d \frac{dt}{dE}$$

from which $I_d = C(dE/dt)$; hence, by integrating, the voltage-current relation for any wave form becomes

$$E = \int \frac{I_d}{C}\, dt$$

For electric circuits, the displacement current in capacitors is the same as the conduction current in the leads to the capacitor so that $I_c = I_d$; therefore, we may express the displacement current in terms of the conduction current.

It is easy to show that the static and dynamic equations for the capacitance, as derived above, are identical. From the static definition, $Q = CE$, and since $Q = \int I\, dt$ it follows that $CE = \int I\, dt$. Hence, by differentiating, $I = C(dE/dt)$, which is the kinetic definition given above.

The capacitance, as defined above, is the total capacitance, since the total electric flux originating on one surface or conducting plate is assumed to flow to the opposite conducting plate or surface. If there are a number of conductors separated by a dielectric and so arranged that the flux from conductor A flows to other conductors, B, C, . . . , N, then the total capacitance of conductor A with respect to all other conductors is given by the expression

$$C_A = \frac{K' \iint_s \mathfrak{D}\cdot ds}{\int_B^A \mathcal{E}\cdot dl} + \frac{K' \iint_s \mathfrak{D}\cdot ds}{\int_C^A \mathcal{E}\cdot dl} + \cdots + \frac{K' \iint_s \mathfrak{D}\cdot ds}{\int_N^A \mathcal{E}\cdot dl}$$

$$= C_{AB} + C_{AC} + \cdots + C_{AN}$$

In devices intended to exhibit primarily the property of capacitance (capacitors or condensers), the capacitance is the total capacitance between two plates or other conductors separated by air, oil, mica, or other suitable gaseous, liquid, or solid dielectric. Partial capacitances are encountered when more than two conductors are separated by a dielectric, as when circuits are coupled through capacitors. It is also encountered in the capacitance between the electrodes of a multielement electron tube, and sometimes these interelectrode capacitances are responsible for undesired behavior of the tube, even though the capacitances are fairly small.

Sometimes it is more convenient to employ another circuit concept, the *elastance*, which is the reciprocal of the capacitance. The elastance, represented by the letter S, may be either the total or the partial elastance, corresponding to the total or the partial capacitance. The total elastance is defined by the electrostatic relation

$$S = \frac{1}{C} = \frac{E}{Q} = \frac{K''E}{\psi} = \frac{K''\int \mathcal{E} \cos\theta\, dl}{\iint_s \mathfrak{D} \cos\theta\, ds} = \frac{K''\int \mathcal{E}\cdot dl}{\iint \mathfrak{D}\cdot ds} = \frac{K''\mathcal{E}\int dl}{\epsilon\mathcal{E}\iint ds} = \frac{K''l}{\epsilon s}$$

or, by the kinetic or dynamic relation,

$$S = \frac{1}{C} = \frac{E}{\int I\, dt}$$

Capacitance is measured in coulombs per volt, to which the name "farad" has been given. The farad is a large value of capacitance for engineering purposes, so that subdivisions of it are more commonly employed. A capacitor has a capacitance of 1 farad when a charge of 1 coulomb is sustained by a difference of potential of 1 volt

between the conductors. The microfarad (10^{-6} farad, abbreviated μf) and the micro-microfarad (10^{-12} farad, abbreviated $\mu\mu f$) are units of capacitance commonly used in radio engineering. Sometimes the abbreviations mf and mmf are used for μf and $\mu\mu f$, but such practice is not in conformity with the usually accepted abbreviations for metric prefixes (see Sec. 170).

The unit of elastance is the reciprocal farad or *daraf*, which is the elastance represented by 1 volt between two conductors whose charge is 1 coulomb.

137. Inductance. Inductance is the (scalar) property of an electric circuit, or of two neighboring circuits, which determines the emf induced in one of the circuits by a change of current in either one.

Self-inductance is the property of an electric circuit that determines, for a given rate of change of current in the circuit, the emf induced in the same circuit, the induced voltage, E, and the self-inductance, L, being related to the current flowing in the same circuit by the relation

$$E_1 = -L\frac{dI_1}{dt}$$

where L is the coefficient of self-inductance.

Mutual inductance is the common property of two associated electric circuits that determines, for a given rate of change of current in one of the circuits, the emf induced in the other. Thus, if the mutual inductance, M, is positive,

$$E_1 = -M\frac{dI_2}{dt}$$

$$E_2 = -M\frac{dI_1}{dt}$$

where E_1 and I_1 are the voltage induced and the current, respectively, in circuit 1, and E_2 and I_2 are the voltage induced and the current in circuit 2, and M is the coefficient of mutual inductance.

138. Self-inductance. The relation between induced voltage, current, and self-inductance may be obtained directly from the definition of self-inductance and induced emf. The inductance is defined as the ratio of the flux linkages to the current, or $L = \Lambda/I = N\phi/I$, whereas the induced emf is equal to the time rate of decrease of flux linkages, or $E = -(d\Lambda/dt) = -[d(N\phi)/dt]$. From the first of these relations we have $N\phi = LI$ and, combining this with the second relation, there results

$$E = -\frac{d(N\phi)}{dt} = -\frac{d(LI)}{dt} = -\left(L\frac{dI}{dt} + I\frac{dL}{dt}\right)$$

If the inductance does not vary with time, the familiar result is obtained

$$E = -L\frac{dI}{dt}$$

The general expression for induced emf may be used to derive the expression for the inductance in a way that gives a somewhat better picture of the physical action taking place. In a multiturn coil of N turns in a magnetic field whose average flux is ϕ webers not all the turns cut all the flux lines even when the turns are close together. If K is the fraction of the flux linkages out of the total maximum number that is possible, the number of actual flux linkages is $KN\phi$. For most coils in radio work (except those in which mutual coupling between portions of the coil is adjustable or variable), K and N are constant. For this special but very common case, the induced voltage is

$$E = -KN\frac{d\phi}{dt}$$

The magnetic flux may be produced by current flowing through the windings of the coil, and in this case the magnetic flux produced is given by $\phi = NI$. Hence the voltage induced in the coil by current flowing through it is given by the relation

$$E = -KN^2\frac{dI}{dt} = -L\frac{dI}{dt}$$

from which $L = KN^2$. From this point of view the self-inductance is an electrical quantity whose magnitude depends upon the square of the number of turns of the coil and also upon the fraction of the total flux linkages that actually exist for the coil in question.

The self-inductance can also be derived from field relations. Provided it is not in a region of ferromagnetic materials, *i.e.*, so long as μ is constant, the inductance is the constant ratio of the magnetic flux linkages to the current flowing. Hence, from the field relations for the steady case, the self-inductance may be defined by the relation

$$L = \frac{\phi}{I} = \frac{\iint_s \mathcal{B}\cos\theta'\, ds}{K'''\int \mathcal{H}\cos\theta\, dl}$$

For a solenoid of N turns (the solenoid being infinitely long so that end effects may be neglected) the number of flux linkages is $KN\phi$, and the self-inductance of the multi-turn coil is then

$$L = \frac{KN\iint_s \mathcal{B}\cos\theta'\, ds}{K'''\int \mathcal{H}\cos\theta\, dl}$$

For a coil whose length, l, is very much greater than its diameter, the value of $\mathcal{B}$ at the central axis is $\mathcal{B} = \mu NI/l$, so that for such a coil the inductance is given by

$$L = \frac{KN\iint_s \frac{\mu NI}{l}\cdot ds}{K'''\int \mathcal{B}\cdot dl} = \frac{KN^2\mu Is}{K'''Il} = \frac{KN^2\mu s}{K'''l}$$

In the form here given, this formula is not useful for computing the self-inductance of solenoids unless the individual factors can be evaluated. Nevertheless, this result is useful for illustrating the physical factors and dimensions upon which the self-inductance of a solenoid depends.

Self-inductance is measured in henrys or convenient decimal submultiples of the henry, such as the millihenry or the microhenry.

A few authors sometimes make use of the reciprocal inductance, designated by the symbol Γ. The reciprocal inductance is, of course, defined to be $\Gamma = I/\phi$ and is measured in reciprocal henrys or *yrnehs*.

139. Mutual Inductance. The determination of mutual inductance requires consideration of two adjacent loops. If the current flows through one coil or loop, it establishes a magnetic field around its own turns, but it also establishes a magnetic field around the adjacent loop or coil in which it induces an emf. Conversely, the current through the second coil sets up a magnetic field which induces an emf in the first coil as well as in its own turns. Let I_1 and I_2 be the current in coils 1 and 2, respectively. Let the magnetic flux linking circuit 2 as a result of current in circuit 1 be ϕ_{21}, and let ϕ_{12} represent the magnetic flux linking circuit 1 as a result of current in coil 2. Then, if K is the fraction of the number of lines of magnetic flux set up by circuit 1 which cuts circuit 2 (or conversely) and if N_1 and N_2 are the number of turns of coils 1 and 2, respectively, the interlinking flux is given by either of the relations

$$\phi_{21} = KN_2I_1 \qquad \text{or} \qquad \phi_{12} = KN_1I_2$$

The coefficient of mutual inductance, M, is defined as the number of flux linkages of one circuit per unit current flowing in the other. Hence, mathematically, the coefficient of mutual inductance is given by

$$M = \frac{N_1\phi_{21}}{I_1} = \frac{N_2\phi_{12}}{I_2} = KN_1N_2$$

The magnitude of the mutual inductance between two circuits depends upon the number of turns in each of the two circuits as well as upon the shapes of the coils, their separation (linear as well as angular), and other factors having a bearing on the flux linkages.

Mutual inductance may be derived from the basic field concepts. The calculations are long and not particularly easy to carry out for any particular physical configuration of conductors. A treatment of this subject may be found in Harnwell.[1]

The units in which mutual inductance is measured are the same as those for self-inductance: the henry and its decimal submultiples. But, whereas self-inductance is a positive quantity, mutual inductance may be either positive or negative.

140. Power Dissipated in a Resistor. If a potential difference, E, is maintained across a semiconductor (resistor), electric charges in the resistor will be set in motion. If a charge, dQ, is set in motion by the potential difference, E, the energy expended in the process is $dU = E\,dQ$, and if this element of charge traverses the resistor in time dt, the power expended in the process is

$$P = \frac{dU}{dt} = E\frac{dQ}{dt} = EI$$

For linear resistors that obey Ohm's law, $E = IR$; hence, the power dissipated in such a resistor is given by

$$P = EI = I^2R = \frac{E^2}{R}$$

The power dissipated will be measured in watts if I is the current in amperes, E is the potential drop in volts, and R is the resistance in ohms.

141. Energy Stored in Dielectric of a Capacitor. Suppose that at any instant of time the potential difference between the conducting elements of a capacitor has built up to the value E as a result of transferring an element of charge, dQ, to the plates or conductors. The amount of energy required for the process is $dU = E\,dQ$. Since, by definition of capacitance, $C = Q/E$, it follows that $Q = CE$ or $dQ = C\,dE$. Hence the energy increment is $dU = E\,dQ = CE\,dE$. Upon integrating, the total energy is found to be

$$U = \int dU = \int_0^E CE\,dE = 0.5CE^2 = 0.5\frac{Q^2}{C}$$

The energy, in mks units, is in joules, E is in volts, Q in coulombs, and C in farads.

142. Energy Stored in Magnetic Field of Inductor. From the relations given in Sec. 137, the drop in potential difference across an inductor is given by the relation $E = L(dI/dt)$, from which is obtained the expression $E\,dt = L\,dI$. The energy expended in time dt is given by the relation $dU = EI\,dt = LI\,dI$. Hence, the total energy in the magnetic field of an inductor is the integral of dU, or

$$U = \int dU = \int_0^I LI\,dI = 0.5LI^2 = 0.5L\left(\frac{dQ}{dt}\right)^2$$

In mks units, the energy is in joules, I is in amperes, L is in henrys, and Q is in coulombs.

[1] Harnwell, G. P., "Principles of Electricity and Electromagnetism," p. 297, McGraw-Hill, 1938.

The voltage-current relations for linear circuit elements such as have been treated here are summarized in Table 11, Sec. 155.

143. Circuit Laws and Theorems. The behavior of electrical circuits can be predicted on the basis of two relations originally stated by Kirchhoff and applicable under all conditions and a relation, originally stated by Ohm, which, although not universally applicable (at least in its simplest form), is true for many instances and is highly important and useful. In addition to these Kirchhoff and Ohm relations, a number of theorems find extensive usefulness in simplifying the calculations of circuit behavior. The most important of these are the principle of superposition, the compensation (substitution) theorem, the reciprocity theorem, the maximum power theorem, Thévenin's theorem, and Norton's theorem. These laws and theorems are treated in the following sections.

144. Kirchhoff's Laws. The two circuit laws of Kirchhoff may be stated as follows:

1. The algebraic sum of the currents flowing toward any point in an electric circuit is zero.
2. The algebraic sum of the product of the current and resistance in each of the conductors in any closed path in an electric circuit is equal to the algebraic sum of the emfs in that path.

As stated here, Kirchhoff's laws apply to the instantaneous values of the current and potential differences, but they may be extended to the effective values of sinusoidal currents and voltages by replacing "algebraic sum" by "vector sum" and replacing the term "resistance" by the term "impedance."

Each of the two Kirchhoff laws gives rise to a separate method of analyzing circuit behavior: the node and the loop method. In the node or junction method, the flow of current of all conductors meeting at a common point must be zero. Hence, if the magnitude and direction of all currents but one are known (or can be assumed), the remaining current can be determined by the application of the Kirchhoff law for current at a junction. In the loop method, the sum of all potential differences must be zero, or the sum of the rises of potential difference must equal the sum of the drops in potential difference.

145. Ohm's Law. Ohm's law states that the current in an electric circuit is directly proportional to the emf in the circuit. This law does not apply to all circuits but to metallic circuits and to many circuits containing electrolytic resistance. Ohm's law was first enunciated for a circuit in which there is constant emf and an unvarying current. It is applicable to circuits in which varying currents flow if account is taken of the induced emf resulting from the self-inductance of the circuit and of the distribution of current in the cross section of the circuit. Ohm's law applies only to linear circuits.

146. Principle of Linear Superposition. According to the principle of superposition, if several causes act simultaneously in a linear system, the resultant effect of all of them is equal to the sum of the individual effects of each cause acting by itself. As applied to electric circuits, the principle may be stated more explicitly. In a linear circuit, each emf acts independently of all other emfs in producing currents in the circuit.

147. Compensation Theorem. The compensation (or substitution) theorem states the conditions under which an emf may be replaced, in an electric circuit, by a potential difference across a resistor, so far as the circuit currents are concerned. Thus, provided the emf equals the potential drop across the resistance and is oppositely directed, a resistance element in a circuit can be replaced by an emf, or vice versa.

148. Reciprocity Theorem. In any branch, A, of an electric circuit, the current produced by an emf acting in another branch, B, is equal to the current in branch B when its emf is transferred to branch A. This is the equivalent of saying that a resistanceless source of emf may be interchanged with a resistanceless current-measuring instrument without altering the reading or indication of the instrument.

149. Maximum Power Transfer Theorem. The maximum amount of electric power is delivered from a source to a load connected to it when the resistance of the load is equal to the internal resistance of the power source. If the source and load contain

reactance as well as resistance, maximum power is transferred from the source to the load when the load resistance is equal to the internal resistance of the source and when the reactance of the load is equal in magnitude but opposite in sign to that of the source. Thus, maximum power is delivered from a source to a load when the load impedance is the conjugate of that of the source.

150. Thévenin's Theorem. If two terminals are available for any linear network, then, so far as external calculations of the system are concerned, they may be regarded as the terminals of a simple series circuit having a resistance equal to the resistance measured between the terminals, and an emf equal to the difference of potential between the two terminals.

151. Norton's Theorem. In a linear circuit, any generator of electric power may be considered equivalent, at specified frequency, to a current generator whose current is equal to the short-circuit current in shunt with an admittance whose magnitude is equal to that which is measured across the generator when the generator is inactive and there is no load connected to it.

152. Electric Networks. An electric network is a system of interconnected circuit elements and sources of emf. The points at which two or more circuit elements are connected are called "nodes" or "junctions." A continuous path (or several conducting paths) through which current may flow is called a "loop."

153. Circuit Connections. Fundamentally, two types of circuits are possible, according to the way in which the circuit elements are joined:

1. In series-connected circuits, the circuit elements are connected, one after the other, in such a way that the same current flows, successively, through each element, and the applied emf is equal to the sum of the drops in potential differences across all the successively connected circuit elements.

2. In parallel- or shunt-connected circuits the circuit elements are connected side by side in such a way that the same emf is applied simultaneously to each and every element, the total current flowing through the circuit being the sum of the currents flowing through each circuit element individually.
FIG. 32. Series circuit containing R, L, and C.
FIG. 33. Parallel circuit containing R, L, and C.

Examples of the most general two-terminal series-connected circuit and the most general two-terminal shunt-connected circuit containing, in each case, one of the three common circuit elements are shown in Figs. 32 and 33, respectively.

Combinations of series-connected circuit elements and shunt-connected circuit elements are possible to give rise to series-shunt or shunt-series circuits of any degree of complexity, but in any case only these two methods of connection are possible for two-terminal circuit elements.

154. Resultant of Series- and Shunt-connected Circuit Elements. Circuit elements connected either in series or in parallel, provided they are all of the same kind, may be replaced by an equivalent circuit element whose circuit parameter is the resultant

of that of the individually connected circuit elements. So long as there is no interaction between the fields of two or more circuit elements, *i.e.*, so long as no coupling exists between two or more circuit elements, the resultant circuit parameter of several like circuit elements connected together is simply expressed.

In the case of series-connected circuit elements, the resultant of several like circuit elements may be determined from the loop equations of Kirchhoff's laws. If subscripts 1, 2, . . . , n designate the component circuit elements connected in series without coupling or field interaction, the resultant circuit parameter, indicated by the subscript T, is given by the following relations:

For resistors,

$$R_T = R_1 + R_2 + R_3 + \cdots + R_n = \sum_{n=1}^{n} R_n$$

For inductors having no mutual coupling,

$$L_T = L_1 + L_2 + L_3 + \cdots + L_n = \sum_{n=1}^{n} L_n$$

For elastors (reciprocal capacitors) having no coupling,

$$S_T = S_1 + S_2 + S_3 + \cdots + S_n = \sum_{n=1}^{n} S_n$$

In the case of parallel-connected circuit elements, the resultant of several like circuit elements may be determined from the node or junction equation of Kirchhoff's laws. If the subscript notation is the same as that used above for series circuits, the resultant circuit parameter, indicated by the subscript T, is given by the following relations:

For conductance elements (reciprocal resistors),

$$G_T = G_1 + G_2 + G_3 + \cdots + G_n = \sum_{n=1}^{n} G_n$$

For reciprocal inductors having no mutual coupling,

$$\Gamma_T = \Gamma_1 + \Gamma_2 + \Gamma_3 + \cdots + \Gamma_n = \sum_{n=1}^{n} \Gamma_n$$

For capacitors having no coupling,

$$C_T = C_1 + C_2 + C_3 + \cdots + C_n = \sum_{n=1}^{n} C_n$$

In each case the resultant circuit element has properties like those of its constituent equivalent elements and is measured in the same electrical units of ohms, henrys, and darafs for the series circuits, and in mhos, yrnehs, and farads for the shunt-connected circuit elements, respectively.

155. Circuit Solutions. The solution for an electric circuit consists in finding the relations between the voltages (rises as well as drops of potential difference) and currents as a function of time. This relationship is determined by means of Kirchhoff's laws and by writing the node or loop equations for the circuit in terms of the general voltage-current relations for circuit elements as given in Table 11, and including any sources of emf that may exist in the circuit.

Since the general voltage-current relations for circuits composed of linear circuit elements are expressible through the use of differential, algebraic, or integral expressions, it is possible to differentiate these expressions with respect to time so that the

circuit behavior is expressed in terms of differential equations that represent the dynamic equilibrium of the circuit.

The complete solution of the differential equation representing the dynamic equilibrium of the electric circuit consists of two parts: (1) a transient (represented or expressed by the particular integral solution of the differential equation) specifying the temporary redistribution of charges (hence, a temporary voltage and current component) resulting from a sudden change in dynamic conditions, and (2) a steady-state solution (expressed by the complementary function of the differential equation) which represents the dynamic equilibrium of the circuit when subjected to an applied emf.

The currents and voltages representing the transient conditions of a network usually decrease rapidly with time and soon become negligible. In the steady-state condition, the voltages and currents may vary cyclically, but their effective value is constant.

Table 11. Voltage-Current and Energy Relations for Circuit Elements

Relation	Relation for the circuit property of		
	Resistance	Inductance	Capacitance
Voltage-current	$E = RI$	$E = L\frac{dI}{dt}$	$E = \frac{1}{C}\int I\,dt$
Current-voltage	$I = \frac{E}{R}$	$I = \frac{1}{L}\int E\,dt$	$I = C\frac{dE}{dt}$
Power dissipation	$P = I^2R = \frac{E^2}{R}$	$P = 0$	$P = 0$
Energy storage	$U = 0$	$U = \frac{1}{2}LI^2$	$U = \frac{1}{2}CE^2$

In the case of a harmonically applied emf, the drops in potential difference across each of the circuit elements and the current through the linear circuit elements are also harmonic functions of time and of the same frequency (but not the same phase, in general) as that of the applied emf. It is not generally true for any wave form, however, that the same wave shape exists for each of the circuit elements in the circuit.

156. Steady-state Solution. The steady-state condition of an electric circuit composed of linear two-terminal elements of R, L, and C is that in which the effective value of the current flowing in the circuit as a result of an applied emf is constant, each cycle of the recurrent wave form being like that of every other cycle. In general, the wave forms of the voltages across the different kinds of circuit elements of a series-connected circuit are unlike those across other circuit elements and, except in the case of a resistor, are not like the wave form of the applied emf. Likewise in shunt-connected circuits, the wave form of current through each circuit element is, in general, different from that flowing through circuit elements of another kind. Except for phase displacements, the wave forms are alike in the special but important case of harmonic voltages and currents. This is a direct consequence of the fact that the derivative and integral of a harmonic function are also harmonic functions.

The determination of the steady-state solution of electric circuits composed of linear circuit elements will be illustrated by finding the current that flows in a series R, L, C circuit when a harmonic emf, $E = E_m e^{j\omega t}$, is impressed across the series circuit of Fig. 32. From Kirchhoff's voltage or loop law and the voltage-current relations for the three kinds of circuit elements in the system, it follows that the loop equation takes the form

$$E = E_m e^{j\omega t} = E_L + E_R + E_C = L\frac{dI}{dt} + RI + \frac{1}{C}\int I\,dt$$

where I is the current flowing in the circuit and whose value is to be determined. Since it is easier to manipulate differential equations than integro-differential equa-

tions, the loop equation above may be transformed into a differential equation by differentiating both sides with respect to t. The result is

$$j\omega E_m e^{j\omega t} = L\frac{d^2I}{dt^2} + R\frac{dI}{dt} + \frac{1}{C}I$$

A solution of this equation is $I = I_m e^{j\omega t}$, from which $(dI/dt) = j\omega I_m e^{j\omega t}$ and $(d^2I/dt^2) = j^2\omega^2 I_m e^{j\omega t}$. Substituting these values in the above equation and dividing both sides by $j\omega$, there is obtained

$$E_m e^{j\omega t} = \left(j\omega L + R + \frac{1}{j\omega C}\right) I_m e^{j\omega t} = ZI_m e^{j\omega t}$$

where $Z = [j\omega L + R + (1/j\omega C)] = R + j[\omega L - (1/\omega C)]$ is the impedance of the circuit. From this result it is evident that current and voltage both vary harmonically with time, as does the voltage drop across each of the circuit elements.

157. Transient Solution. The transient condition of an electric circuit composed of linear elements of R, L, and C is that which involves the temporary redistribution of charges as the result of a sudden alteration of the dynamic equilibrium of the electric circuit. Since this transient condition expresses a readjustment of the dynamic equilibrium circuit, the solution does not involve any continuously externally applied emf or current. It does, however, involve the initial conditions of the circuit at the time when the circuit equilibrium is disturbed. The wave forms of voltage and current depend not only upon what elements are present in the circuit but also upon the relative magnitudes of the parameters of the circuit elements in the system.

The transient solution of electric circuits will be illustrated by finding the transient current that flows in a series circuit of linear R, L, and C circuit elements, when the quiescent equilibrium of the system is suddenly disturbed by closing the circuit with a battery of time-invariant emf, E, in the circuit. Physically, the circuit represents the charge on a capacitor in a circuit also containing inductance and resistance, under the assumption that the initial charge on the capacitor is zero.

At any instant of time, the Kirchhoff loop equation requires that

$$E = E_L + E_R + E_C = L\frac{dI}{dt} + RI + \frac{1}{C}\int I\,dt$$

To transform this to a differential equation, differentiate with respect to t to obtain

$$\frac{dE}{dt} = 0 = L\frac{d^2I}{dt^2} + R\frac{dI}{dt} + \frac{1}{C}I$$

the general solution of which is

$$I = \left[\frac{E}{\left(R^2 - \frac{4L}{C}\right)^{1/2}}\right] \epsilon^{-(Rt/2L)} \left[\epsilon^{\frac{1}{2L}\sqrt{R^2 - \frac{4L}{C}}\,t} - \epsilon^{-\frac{1}{2L}\sqrt{R^2 - \frac{4L}{C}}\,t}\right]$$

From this solution, it is evident that the term with the negative exponent indicates that the transient current will approach zero for a sufficiently large value of time, approaching zero current at infinite time. But the manner in which this zero current is approached depends upon the relative values of R, L, and C, and three different cases may exist for this circuit:

1. If $R^2 > 4L/C$, the exponential terms in the brackets are positive numbers; the current begins at zero, rises to a maximum value, and then gradually decays to zero slowly, without changing polarity.

2. If $R^2 = 4L/C$, the solution above becomes indeterminate, but by differentiating both numerator and denominator individually with respect to the factor that is the coeffi-

cient of t, the solution for the current is

$$I = \left(\frac{Et}{L}\right) e^{-(Rt/2L)}$$

For this case, often called the "critical" case, the current begins at zero, rises to a maximum value, and returns again to zero without changing polarity. This is the limiting condition of case 1 in which the rise and fall occur more slowly than for the present critical case.

3. If $R^2 < 4L/C$, the current takes the form

$$I = \left(\frac{2E}{\sqrt{\frac{4L}{C} - R^2}}\right) e^{-(Rt/2L)} \sin \omega t$$

where $\omega = \frac{1}{2L}\left(\frac{4L}{c} - R^2\right)^{\frac{1}{2}}$. For this case it is evident from the equation above that the current oscillates with an angular velocity ω and that the amplitude steadily decreases with time until the magnitude of the transient oscillations becomes negligible, ultimately reaching zero at infinite time.

Transients are assuming increasing importance in radio engineering design, and the following list of references will serve as a suitable introduction to this topic.

158. Impedance, Resistance, and Reactance. The impedance of an electric circuit, or portion of an electric circuit, to a completely specified periodic potential difference and current is the ratio of the effective or rms value of the potential difference across the circuit to the effective value of the current flowing through it, there being no source of power in the portion under consideration. The impedance is designated by the letter symbol Z, and if E_{rms} and I_{rms} are the effective values of the potential drop and the current of the circuit, the circuit impedance is given by

$$Z = \frac{E_{\text{rms}}}{I_{\text{rms}}}$$

The impedance is measured in ohms.

If the periodic emf applied to the circuit is composed of components of different frequency, if $E_0, E_1, E_2, \ldots, E_n$ represent the effective values of voltages of frequencies $0, \omega, 2\omega, \ldots, n\omega$, if $I_0, I_1, I_2, \ldots, I_n$ represent the effective values of the currents of the same frequencies, respectively, and if the maximum values of the voltage are $E_0, E_{1m}, E_{2m}, \ldots, E_{nm}$ and the maximum (amplitude) values of the currents are $I_0, I_{1m}, I_{2m}, \ldots, I_{nm}$, then the impedance of the circuit or portion of the circuit is given by the relation

$$Z = \frac{E_{\text{rms}}}{I_{\text{rms}}} = \frac{\sqrt{2E_0^2 + E_{1m}^2 + E_{2m}^2 + \cdots}}{\sqrt{2I_0^2 + I_{1m}^2 + I_{2m}^2 + \cdots}} = \frac{\sqrt{E_0^2 + E_1^2 + E_2^2 + \cdots}}{\sqrt{I_0^2 + I_1^2 + I_2^2 + \cdots}}$$

The impedance thus defined is a scalar quantity and gives merely the ratio of the magnitudes of the voltage and current.

The vector impedance of an electric circuit, or portion of a circuit, for simple harmonic voltage and current is the ratio of the corresponding complex harmonic potential difference to the corresponding complex current. In the example given in Sec. 156, the applied harmonic voltage is $E = E_m e^{j\omega t}$ and the resulting current is $I = I_m e^{j\omega t}$ and the vector impedance, *i.e.*, the impedance expressed as a vector in rectangular coordinates, is

$$Z = \frac{E_m e^{j\omega t}}{I_m e^{j\omega t}} = \left[R + \left(j\omega L + \frac{1}{j\omega C}\right)\right] = \left[R + j\left(\omega L - \frac{1}{\omega C}\right)\right] = R \pm jX$$

where R is the resistance, $j\omega L$ is the inductive reactance in ohms, $1/j\omega C = -j/\omega C$ is the capacitive reactance in ohms, and $X = j\left(\omega L - \frac{1}{\omega C}\right)$ is the reactance in ohms. Depending upon whether the inductive or the capacitive reactance has the larger magnitude, the net reactance will be, respectively, positive or negative, but the resistance will always be positive for linear dissipative circuits.

In the above expression the impedance has been given in rectangular components, R and X, but the impedance may also be expressed in polar coordinates in terms of the magnitude of the impedance, $|Z|$, and the angle of phase shift, $\underline{/\theta}$, of the impedance. Thus, in polar coordinates, the impedance for the series R, L, C circuit is

$$Z = |Z|\underline{/\theta} = \sqrt{R^2 + \left(\omega L - \frac{1}{\omega C}\right)^2} \Bigg/ \tan^{-1} \frac{R}{\left(\omega L - \frac{1}{\omega C}\right)}$$

$$= \sqrt{R^2 + X^2}\ \underline{/\tan^{-1}}\ (R/X)$$

where $|Z| = \sqrt{R^2 + X^2}$ and $\theta = \tan^{-1}(R/X)$. Conversely, the rectangular components of the impedance, in terms of the polar components, are

$$R = |Z| \cos \theta$$
$$X = |Z| \sin \theta$$

Physically the impedance of a circuit is the opposition to the flow of a periodic current under steady-state conditions. It is composed of two parts: a resistive component usually regarded as constant (although the resistance is, strictly speaking, a function of frequency) and a reactive component whose magnitude usually varies appreciably with frequency. Over a sufficiently large frequency range the sign of the reactance also changes. The resistive component accounts for the absorption or dissipation of power. The reactive component results from properties of inductors and capacitors that involve the energy storage and rate-of-change relationships between voltage and current. For ideal circuit elements the reactance determines the frequency-selective properties of the circuit.

The impedance is an electrical quantity whose use is most convenient in solving electrical circuits with circuit elements connected in series.

159. Admittance, Conductance, and Susceptance. The admittance of an electric circuit is the reciprocal of the impedance; it is, therefore, the ratio of the effective value of the current through a circuit or portion of a circuit to the effective value of the potential difference across the circuit, for a completely specified periodic applied voltage. The admittance is designated by the letter Y and is measured in reciprocal ohms or mhos or its multiples or submultiples.

If E_{rms} and I_{rms} are the effective values of the voltage and current, respectively, the admittance is given by

$$Y = \frac{I_{\text{rms}}}{E_{\text{rms}}}$$

For a nonharmonic periodic voltage, the admittance may be determined in a manner similar to that for determining the impedance of a circuit in which nonharmonic current flows.

In any electric circuit whose resistive and reactive components are R and X, respectively, the corresponding admittance is given by the relation

$$Y = \frac{1}{Z} = \frac{1}{R \pm jx} = \frac{1}{R \pm jx} \cdot \frac{R \mp jx}{R \mp jx} = \frac{R}{R^2 + X^2} \mp j \frac{X}{R^2 + X^2} = G \mp jB$$

where $G = R/(R^2 + X^2) = R/Z^2$ is the conductance of the circuit (measured in mhos) and $B = \pm X/(R^2 + X^2) = X/Z^2$ is the susceptance of the circuit (measured in mhos).

The admittance may be expressed in polar components as well as in the rectangular components given above. In polar components,

$$Y = |Y|\underline{/\phi} = \sqrt{G^2 + B^2}\ \underline{/\tan^{-1} (B/G)}$$

where $|Y| = \sqrt{G^2 + B^2}$ and $\phi = \tan^{-1} (B/G)$. Conversely, the rectangular components of the admittance, in terms of polar components, are

$$G = |Y| \cos \phi$$
$$B = |Y| \sin \phi$$

Since impedance and admittance are reciprocally related, the impedance may be expressed in terms of admittance components just as admittance was expressed, above, in terms of impedance components. Thus, in terms of the admittance, the impedance is

$$Z = \frac{1}{Y} = \frac{1}{G \pm jB} = \frac{1}{G \pm jB} \cdot \frac{G \mp jB}{G \mp jB} = \frac{G}{G^2 + B^2} \mp j \frac{B}{G^2 + B^2}$$

Physically, the admittance expresses the ease with which the current flows through a circuit. It is composed of two parts: a conductance component, which is usually regarded as constant and which enters into determinations of power, and a susceptive component, which usually varies appreciably with frequency in a manner inverse to that of the reactance of the circuit.

Admittance is a concept that is most useful in dealing with parallel circuits.

160. Resonance. Resonance exists between one coordinate of a system that is executing oscillations or vibrations and a periodic agency that maintains the oscillations or vibrations when a small amplitude of the periodic agency produces in the system a relatively large amplitude of the oscillation or vibration.

Amplitude resonance exists when the resonance is such that any change in the period of the periodic agency without changing its amplitude produces a decrease in the amplitude of the oscillation or vibration of the system.

Period or natural resonance exists when the resonance is such that the period of the applied agency is the same as the natural period of oscillation or vibration of the system.

Phase or velocity resonance exists when the resonance is such that the angular phase difference between the fundamental components of the oscillation or vibration and of the applied agency is 90 deg ($\pi/2$ radians). With phase resonance, the time derivative of the coordinate that is in resonance is a maximum.

Resonance may exist in an electric circuit possessing inductance, resistance, and capacitance between the quantity of electricity that oscillates and a periodically applied emf that sustains the oscillations. Any one of three kinds of resonance, *viz.*, amplitude resonance, period resonance, or phase resonance, may exist depending upon the constants of the circuit. In electric circuits having a high degree of selectivity, there is little distinction between the three kinds of resonance.

In a series circuit composed of linear circuit elements of R, L, and C, resonance is obtained when the net reactance is 0 or when $\omega L = 1/\omega C$. Hence, the frequency of resonance is obtained from the relation $\omega^2 = 1/(LC)$ so that

$$f_r = \frac{1}{2\pi \sqrt{LC}}$$

The frequency will be expressed in cycles per second if L is inductance in henrys and C is capacitance in farads.

MAGNETIC CIRCUITS

161. Electric and Magnetic Circuits. A magnetic circuit is a closed path of magnetic flux, the path having the direction of the magnetic induction at every point. On the other hand, an electric circuit is a closed path of electric current, the path having the direction of the electric current at every point. Although the equations for electric and magnetic circuits may take the same mathematical form, the analogy between them expresses no physical correspondence. Particularly is this true for magnetic induction, which does not represent a dissipation of power, whereas the flow of electric current does.

Corresponding to the relation between voltage, current, and resistance, as given by Ohm's law for an electric circuit, the magnetic circuit relation may be written

$$\mathfrak{F} = \phi \mathfrak{R}$$

where $\mathfrak{F}$ is the magnetomotive force in ampere-turns in the mks system, ϕ is the magnetic flux or induction in webers, and $\mathfrak{R}$ is the reluctance of the magnetic circuit in ampere-turns per weber. An unvarying magnetic flux is regarded as a static condition, whereas in the equivalent electric circuit, the steady current is the uniform flow of electric charges. Reluctance is not analogous to resistance in the sense of accounting for energy dissipation. Another difference between electric and magnetic circuits is the degree to which electric or magnetic effects are confined to their respective circuits. Whereas excellent insulators for the flow of electric conduction current exist, there is no insulator for magnetic induction; therefore, the magnetic flux is not so completely confined to its magnetic circuit as the conduction current is confined to the electric circuit. From the practical point of view, the most useful magnetic circuits consist mainly of ferromagnetic materials, and for such materials, the reluctance is not constant; in this respect too, magnetic circuits differ from most electric circuits for which Ohm's law is obeyed.

162. Magnetic Permeability and Reluctivity. Permeability is the property of an isotropic medium which, under specified conditions, determines the relation between the magnitudes of the magnetizing force and the magnetic induction of the medium. Under the specified conditions, permeability is measured as the ratio of the magnetic induction to the magnetizing force, or

$$\mu = \frac{\mathfrak{B}}{\mathfrak{H}}$$

where, in mks units, $\mathfrak{B}$ is the magnetic flux density or induction in webers per square meter, and $\mathfrak{H}$ is the magnetic field intensity in ampere-turns per meter.

The relative permeability of most substances does not differ appreciably from that of vacuum, which is taken as unity. For practical purposes the relative permeability is constant, independent of the flux density. Iron, nickel, steel, cobalt, and magnetic alloys—the materials of practical importance in magnetic circuits—have relative permeabilities appreciably greater than unity, and the permeability varies considerably with the magnetizing force or the flux density, with the composition, and with the previous heat-treatment of the magnetic material.

For a uniform magnetic path, the reluctance may be determined from the field expressions for the magnetomotive force and magnetic flux,

$$\mathcal{R} = \frac{\mathcal{F}}{\phi} = \frac{\int \mathcal{H} \cos\theta \, dl}{\iint_s \mathcal{B} \cos\theta' \, ds} = \frac{\mathcal{H} \int dl}{\mu \mathcal{H} \iint_s ds} = \frac{l}{\mu s} = \nu \frac{l}{s}$$

where $\mathcal{F}$ is the magnetomotive force in ampere-turns, ϕ is the magnetic flux in webers, $\mathcal{H}$ is the magnetic field intensity in ampere-turns per weber, θ is the angle between $\mathcal{H}$ and l or the angle between the direction of $\mathcal{B}$ and the normal to the surface s and for this case has the value $\theta = 0$, μ is the permeability in henrys per meter, and $\nu = 1/\mu$ is the reluctivity in meters per henry. For nonmagnetic substances (vacuum, air, and so on) the permeability and reluctivity are usually written μ_v and ν_v.

In some magnetic circuits, there are varying as well as steady components of magnetic flux. The permeability offered to the varying component of the magnetizing force superimposed upon the steady component of the magnetizing force is called the "incremental permeability," the "apparent permeability," or sometimes the "a-c permeability." For such cases the magnetization cycle follows a small displaced hysteresis loop. The incremental permeability is measured by the slope of the straight line connecting the end points of this hysteresis loop. The incremental permeability decreases with increasing magnetization due to the steady component of magnetizing force and, up to the point at which saturation occurs, increases with the magnitude of the time-varying component of the magnetic flux density.

163. Reluctance and Permeance in Series and Parallel Magnetic Circuits. Permeance of a magnetic circuit is the reciprocal of the reluctance and expresses the ease with which magnetic flux may be established in a magnetic circuit, whereas reluctance is a measure of the opposition or difficulty with which magnetic flux is established in the magnetic circuit.

For magnetic circuits in series with one another, the total reluctance is the sum of the reluctances of the individual circuits, plus the reluctance of the joints where the magnetic circuits of high permeability are joined. If magnetic circuits are placed in parallel with one another, the permeance of each circuit is added to ascertain the total or net permeance of the combination of magnetic circuit branches in parallel.

ELECTROMAGNETIC WAVES

164. Electromagnetic Waves. A wave is a disturbance that is propagated in a medium in such a way that, at any point in the medium, the displacement of the wave is a function of the position of the point. Any physical quantity that has the same relationship to some independent variable (usually time) that a propagated disturbance has at a particular instant, with respect to space, may be called a "wave." The acceleration of electric charges is capable of producing waves in the electromagnetic

field, and it is these electromagnetic waves that make possible radio communication without the intervention of physical conductors between the transmitting and the receiving stations.

Maxwell's equations express the general relations between electrical and magnetic quantities, *i.e.*, between $\mathcal{E}$, $\mathcal{D}$, $\mathcal{H}$, and $\mathcal{B}$; hence, the Maxwell equations may be expected to yield the means for deriving the equations of electromagnetic waves. This is indeed the case, but the variables are interconnected in such a manner that Maxwell's differential equations must be simplified (by separating the variables) before any solutions for electromagnetic waves can be ascertained. When the variables have been properly separated for the four Maxwell field equations through suitable mathematical manipulations, it is next required to find the relation or relations connecting time and the directional derivatives of $\mathcal{E}$, $\mathcal{D}$, $\mathcal{H}$, and $\mathcal{B}$, such that all four field equations are simultaneously satisfied and that the time-space relations will be in accordance with the definitions above for the propagation of electromagnetic waves. Since the first two (divergence) field equations do not involve time functions, the procedure is essentially that of finding a solution to the two circuital equations, both of which must be simultaneously satisfied.

In a medium that is perfectly insulating (zero conductivity) and free from charge density (free space satisfies these two conditions), the field equations to be solved, when time and space variables have been separated, are, in rectangular coordinates,

$$\mathbf{i}\frac{\partial \mathcal{E}_x}{\partial x} + \mathbf{j}\frac{\partial \mathcal{E}_y}{\partial y} + \mathbf{k}\frac{\partial \mathcal{E}_z}{\partial z} = 0$$

$$\mathbf{i}\frac{\partial \mathcal{H}_x}{\partial x} + \mathbf{j}\frac{\partial \mathcal{H}_y}{\partial y} + \mathbf{k}\frac{\partial \mathcal{H}_z}{\partial x} = 0$$

$$\mathbf{i}\left(\frac{\partial^2 \mathcal{E}_x}{\partial x^2} + \frac{\partial^2 \mathcal{E}_x}{\partial y^2} + \frac{\partial^2 \mathcal{E}_x}{\partial z^2}\right) = \mu\epsilon\frac{\partial^2 \mathcal{E}_x}{\partial t^2}$$

$$\mathbf{j}\left(\frac{\partial^2 \mathcal{E}_y}{\partial x^2} + \frac{\partial^2 \mathcal{E}_y}{\partial y^2} + \frac{\partial^2 \mathcal{E}_y}{\partial z^2}\right) = \mu\epsilon\frac{\partial^2 \mathcal{E}_y}{\partial t^2}$$

$$\mathbf{k}\left(\frac{\partial^2 \mathcal{E}_z}{\partial x^2} + \frac{\partial^2 \mathcal{E}_z}{\partial y^2} + \frac{\partial^2 \mathcal{E}_z}{\partial z^2}\right) = \mu\epsilon\frac{\partial^2 \mathcal{E}_z}{\partial t^2}$$

$$\mathbf{i}\left(\frac{\partial^2 \mathcal{H}_x}{\partial x^2} + \frac{\partial^2 \mathcal{H}_x}{\partial y^2} + \frac{\partial^2 \mathcal{H}_x}{\partial z^2}\right) = \mu\epsilon\frac{\partial^2 \mathcal{H}_x}{\partial t^2}$$

$$\mathbf{j}\left(\frac{\partial^2 \mathcal{H}_y}{\partial x^2} + \frac{\partial^2 \mathcal{H}_y}{\partial y^2} + \frac{\partial^2 \mathcal{H}_y}{\partial z^2}\right) = \mu\epsilon\frac{\partial^2 \mathcal{H}_y}{\partial t^2}$$

$$\mathbf{k}\left(\frac{\partial \mathcal{H}_z}{\partial x^2} + \frac{\partial^2 \mathcal{H}_z}{\partial y^2} + \frac{\partial^2 \mathcal{H}_z}{\partial z^2}\right) = \mu\epsilon\frac{\partial^2 \mathcal{H}_z}{\partial t^2}$$

Only electromagnetic waves that (when expressed in rectangular coordinates) satisfy these equations are possible; the equations above may, therefore, be used to determine the required form of the fields for wave propagation.

Solution of the above equations requires that each directional component of the electric or magnetic field intensity be of the form

$$\left.\begin{matrix}\mathcal{E}\\ \mathcal{H}\end{matrix}\right\} = f\left(t - \frac{l}{v}\right) + f\left(t + \frac{l}{v}\right)$$

where v is the velocity of propagation and is given by $v = 1/\sqrt{\mu\epsilon}$, l is used generically to designate a distance in any of the three orthogonal directions, and the functions, f, represent any single-valued functions. For propagation in free space, the propagation velocity has the special value of the velocity of light, approximately 3×10^8 m

per sec obtained from the relation $v = c = 1/\sqrt{\mu_0\epsilon_0}$. The fact that the functions, f, are arbitrary functions of time makes it possible for the electromagnetic waves to be formed in such a way as to be capable of representing intelligence The fundamental problem of radio communication is to make the time variations of the electromagnetic wave conform to the variations of the intelligence to be transmitted.

The energy stored in the electromagnetic field travels with the wave from the source of the disturbance outward into space, and this phenomenon is the mechanism by which the transmission of electric power, sufficient to carry on communication, occurs. An important point regarding the transmission of electromagnetic waves through space is that the energy is propagated through a dielectric; no conduction can occur in the (ideal) dielectric of free space. The mechanism of propagation is, briefly, that the variations of electric field intensity give rise to variations of magnetic field intensity which, in turn, give rise to variations of the electric field intensity once more, and so on. Once established, the original disturbance is sustained by the mutual interaction of electric and magnetic components of the electromagnetic field as the wave travels through space with the velocity of light. The amplitude of the variations of the electromagnetic field decreases with distance from the center of the disturbance as the wave expands to greater and greater size.

165. Energy in the Electromagnetic Field. Since, as noted above, the energy of the electromagnetic field radiates outward into space, it is desirable to have quantitative expressions for the field energy. Such expressions can be obtained from energy relations derived in Secs. 141 and 142 by converting the circuital relations into field relations.

From the relation giving the total energy stored in the dielectric of a capacitor, the total electric energy stored in an electromagnetic field of volume v is

$$U_{\mathcal{E}} = 0.5CE^2 = 0.5QE = 0.5K''\left(\iint_s \mathfrak{D}\cdot ds\right)\cdot\left(\int \mathcal{E}\cdot dl\right)$$
$$= 0.5K''\left(\iint_s \epsilon\mathcal{E}\cdot ds\right)\cdot\left(\int \mathcal{E}\cdot dl\right) = 0.5K''\epsilon\mathcal{E}^2\iiint dv = 0.5K''\epsilon\mathcal{E}^2 v$$

so that the electric energy per unit volume of field is

$$u_{\mathcal{E}} = 0.5K''\epsilon\mathcal{E}^2$$

In a similar way, by making use of the energy in the magnetic field surrounding a coil, the total magnetic energy stored in an electromagnetic field of volume v is

$$U_{\mathcal{H}} = 0.5LI^2 = 0.5\left(\frac{K''\iint_s \mathfrak{D}\cdot ds}{\int \mathcal{H}\cdot dl}\right)\cdot\left(\int \mathcal{H}\cdot dl\right)^2$$
$$= 0.5K''\left(\iint_s \mu\mathcal{H}\cdot ds\right)\cdot\left(\int \mathcal{H}\cdot dl\right) = 0.5K''\mu\mathcal{H}^2\iiint dv = 0.5K''\mu\mathcal{H}^2 v$$

so that the magnetic energy per unit volume is

$$u_{\mathcal{H}} = 0.5K''\mu\mathcal{H}^2$$

The total energy, per unit volume, is the sum of the electric and magnetic energy, or

$$u = u_{\mathcal{E}} + u_{\mathcal{H}} = K''(0.5\epsilon\mathcal{E}^2 + 0.5\mu\mathcal{H}^2)$$

166. Poynting's Vector. Poynting's vector has importance in the determination of power flow throughout space; it is, therefore, frequently encountered in radiation phenomena. Usually designated by the letter S, it represents the energy per second flowing per unit area perpendicular to the direction of propagation.

At a point in space, the total flow of power (or energy per unit time) is equal to the product of the electric field intensity and the current density (representing a dissipation of power) plus the time rates of change of the magnetic field and the electric field.

Mathematically, in terms of Poynting's vector, S,

$$-\text{div } S = \mathcal{J}\mathcal{E} + \frac{\partial u_{\mathcal{E}}}{\partial t} + \frac{\partial u_{\mathcal{H}}}{\partial t}$$

This equation defines conditions at a point in the electromagnetic field, but it is possible to define the same conditions for a volume, dv. Thus, by expressing $\mathcal{J}$, $\mathcal{E}$, and $\mathcal{H}$ in terms of their orthogonal components, we obtain the integral expression for rectangular coordinates,

$$-\iiint_v \left(\frac{\partial s_x}{\partial x} + \frac{\partial s_y}{\partial y} + \frac{\partial s_z}{\partial z}\right) dv = \iiint_v (\mathcal{J}_x\mathcal{E}_x + \mathcal{J}_y\mathcal{E}_y + \mathcal{J}_z\mathcal{E}_z)\, dv$$
$$+ \iiint_v \frac{\partial}{\partial t}\left(\frac{\epsilon\mathcal{E}_x^2}{2} + \frac{\epsilon\mathcal{E}_y^2}{2} + \frac{\epsilon\mathcal{E}_z^2}{2}\right) dv + \iiint_v \frac{\partial}{\partial t}\left(\frac{\mu\mathcal{H}_x^2}{2} + \frac{\mu\mathcal{H}_y^2}{2} + \frac{\mu\mathcal{H}_z^2}{2}\right) dv$$

167. Boundary Conditions for Electric and Magnetic Fields. In order that any electromagnetic field distribution may be realized physically, it must satisfy Maxwell's equations. In addition it must also satisfy boundary conditions for the physical system in which the electrical effects take place.

FIG. 34. Boundary conditions for electric and magnetic fields.

Whenever an electromagnetic field or wave meets a boundary between two mediums of different dielectric or magnetic properties, there is a change in the fields and, in general, the wave splits into two components, one of which is reflected back into the first medium, the other being refracted into the second medium. For any two mediums, 1 and 2, the tangential components of the electric field and also of the magnetic field are equal on both sides of the dividing surface. Hence, as shown in Fig. 34, the relation exists that

$$\mathcal{E}_{1_T} = \mathcal{E}_{2_T} \qquad \text{and} \qquad \mathcal{H}_{1_T} = \mathcal{H}_{2_T}$$

The relationship between the normal components may be determined from Gauss's law. If the surface charge density of the surface separating the two mediums is σ, then the relation exists that

$$\mathfrak{D}_{1_n} - \mathfrak{D}_{2_n} = \sigma$$

If, as is often the case, the surface charge density is zero, then the above relation simplifies to

$$\mathfrak{D}_{1_n} = \mathfrak{D}_{2_n}$$

From similar reasoning it can be shown that for the magnetic field, for which no free magnetic poles exist, the required relation is

$$\mathcal{B}_{1_n} = \mathcal{B}_{1_n}$$

UNITS AND DIMENSIONS

168. Nature of Units. Quantities of many kinds (mechanical, thermal, chemical, physiological, etc.) are encountered in scientific and engineering work. The magnitudes of different quantities are recorded or compared with one another by selecting some magnitude as unity and expressing all others of the same quantity as a ratio to the unit quantity or magnitude. Hence, any quantity is composed of two parts: (1) a numeric which expresses the relative magnitude of the quantity in terms of the established unit magnitude, and (2) a statement designating the kind of measurement that the quantity represents. For example, the velocity of 3 m per sec contains these two parts: the numeric 3 indicates that the quantity in question has a magnitude 3 times that of unit magnitude in the system of measurement under discussion, and the kind of quantity is indicated by the measure of meters per second, having the dimensions of length divided by time.

Each quantity selected as a reference unit must be established by a physical standard of some kind, or, alternatively, it must be obtained or derived from combinations of other units that are selected or recognized as standard units. The units may be artificial or natural.

For engineering use, two general systems of mechanical units are in use in the United States. The English system of units, most frequently used, is based on the custom of common law and common and generally widespread use. The metric system of units, on the other hand, is legalized by an act of Congress of July 28, 1866. The metric system is extensively used in scientific work because of its simplicity and the ease with which decimally related quantities may be converted from one set of units to another.

169. English Units. Long usage and custom have lent a considerable weight of authority to the English system of units in the United States, in spite of the unnatural and unrational relationships that exist between the various quantities in this system. Because of the unnecessary complication of the oddly related units, the English system has found little support in scientific circles. In engineering work, which is more closely related to the everyday commercial transactions than is scientific work, the English system of units is encountered to such an extent that familiarity with it is requisite. The English system is based on the foot as the unit of length, the second as the unit of time, and the slug as the unit of mass.

170. Metric Units. The metric system, which finds extensive application throughout the scientific world, is based primarily upon the prototype standards of mass and length preserved at the International Bureau of Weights and Measures at Sèvres, France. Similar standards of length and mass are deposited in numerous national laboratories and serve to define the legal standards for all the nation.

Table 12. Metric Prefixes

Name of prefix	Symbol	Multiplying factor
mega-	M	1,000,000
kilo-	k	1,000
hecto-	..	100
deka-	..	10
......	..	1
deci-	..	0.1
centi-	c	0.01
milli-	m	0.001
micro-	μ	0.000,001

A great convenience of the metric system is that all units are expressed in decimal multiples or submultiples of the unit selected for the standard or reference value. The decimal multiples or submultiples are designated in Table 12. Combinations of these prefixes may be used to designate intermediate values; for example, millimicro may be used to designate 0.000,000,001.

171. Fundamental Units and Dimensions. All engineering quantities may be expressed in terms of a comparatively few quantities that are basic or fundamental. In mechanical units, the fundamental quantities are length, mass, time, and angle. In general, each of these dimensions has a different unit or reference standard in the metric system than in the English system. The name of the unit of measurement is usually sufficient to designate the system as well as the unit of measurement in question. Electrical quantities are usually completely specified in terms of three mechanical units and one electrical quantity (although other combinations are possible) so that mechanical units provide a basis for understanding the fundamental properties of electrical quantities.

For quantities that are derived from, or are more complicated than, the elementary or fundamental quantities, the term "dimension" is used in a slightly different sense than its usual one. In the case of derived units, each new physical quantity gives rise to a new dimension or to a new combination of fundamental quantities to express the new physical quantity. For example, in terms of the fundamental quantities of mass, length, time, and angle, area may be expressed as the product of length and length, so that the dimensions of area are length squared, or, more compactly, $s = l^2$.

Table 13. Mechanical Units and Dimensions

Name	Symbol	Dimensions $m^A l^B t^C \theta^D$				Equivalent magnitudes		
		A	B	C	D	Mks units	Cgs units	English units
Length	l	0	1	0	0	1 m	100 cm	3.281 ft
Mass	m	1	0	0	0	1 kg	1,000 g	2.2046 lb
Time	t	0	0	1	0	1 sec	1 sec	1 sec
Angle	θ	0	0	0	1	1 radian	1 radian	1 radian
Area	s	0	2	0	0	1 sq m	10,000 sq cm	10.76 sq ft
Volume	V	0	3	0	0	1 cu m	10^6 cu cm	35.31 cu ft
Velocity	v	0	1	−1	0	1 m/sec	100 cm/sec	3.281 ft/sec
Acceleration	a	0	1	−2	0	1 m/sec²	100 cm/sec²	3.281 ft/sec²
Density	..	1	−2	0	0	1 kg/m²	0.1 g/cm²	0.2048 lb/ft²
Force	f	1	1	−2	0	1 newton	10^5 dynes	723.30 poundals
Pressure	p	1	−1	−2	0	1 newton/m²	10^3 dynes/cm²	67.222 poundals/ft²
Work (energy)	w	1	2	−2	0	1 joule	10^7 ergs	0.7376 ft-lb
Power	P	1	2	−3	0	1 watt	10^7 ergs/sec	0.7376 ft-lb/sec
Momentum	mv	1	1	−1	0	1 kg-m/sec	10^5 g-cm/sec	7.233 lb-ft/sec
Angular velocity	..	0	0	−1	1	1 radian/sec	1 radian/sec	1 radian/sec
Angular acceleration	..	0	0	−2	1	1 radian/sec²	1 radian/sec²	1 radian/sec²

In another example velocity $v = l/t$, or the ratio of the length to the time has the dimensions of lt^{-1}; acceleration has the dimensions lt^{-2}, force mlt^{-3}, and so on.

In Table 13 are given the more important mechanical units and dimensions in the mks, cgs, and English systems.

172. Electrical Units and Dimensions. Electrical energy and power, being primarily thought of as mechanical in their properties, can be expressed in terms of dimensions which are strictly mechanical and which are given in Table 14. Other electrical quantities cannot be expressed in terms of mechanical units alone but require at least one other (electrical) dimension for their specification. The electrical quantity selected for such dimensional analysis may be arbitrarily chosen. Proposals have been made to select, as the fourth unit, that of charge, current, resistance, or the permeability of free space, and perhaps other quantities as well, as recorded in the excellent treatment by Jauncey and Langsdorf.[1] For developing a philosophy relating all derived quantities in terms of fundamental concepts, the charge is the most logical

[1] Jauncey, G. E. M., and A. S. Langsdorf, "MKS Units and Dimensions," Macmillan, 1940.

fourth unit, although resistance is more suitable for laboratory purposes where working standards are to be maintained. Electrical quantities can be expressed in terms of more than one fundamental electrical concept, with a consequent reduction in the number of mechanical quantities that are then required as fundamental. One system that has been proposed is to omit mass as a fundamental quantity in building up a system of electrical dimensions in which the fundamental quantities would be resistance, current, length, and time. No matter what four quantities are selected as the basis of electrical dimensions, they may be expressed in metric (cgs or mks) or English units; they may also be rationalized or unrationalized depending upon whether the factor 4π (resulting from a fundamental property of space) is missing from expressions for force or potential or whether it is missing from expressions for flux, magnetomotive force, and the field equations.

Table 14 lists the more important electrical quantities together with their dimensions and method of expression in several systems of measurement. The mks system of units is regarded as basic since this system has been standardized or established by international agreement and has the further advantage that its units are, in most cases, the units of practical engineering use. The question of rationalization has not yet been definitely settled, but by using the factors of Table 6 (Sec. 94) the relations of Table 14 apply for either the rationalized or the unrationalized system.

173. Comments on Units and Dimensions. The system of units and dimensions encountered in electrical work is apt to be quite confusing because of the numerous systems of measurement and the various proposals that have been made from time to time. The mks system is the only one that meets the requirements of the scientific worker and the practical engineer alike, and since it has been adopted by international agreement, it appears destined to replace the older cgs systems. The mks system of units eliminates the confusion introduced by the constant of proportionality (numerically equal to the velocity of light in free space), which relates the cgs electrostatic and the cgs electromagnetic systems of units.

The question of electrical dimensions and units is an extensive one and cannot be adequately treated here.

CHAPTER 2

RESISTANCE

By Jesse Marsten[1]

1. General Concepts. In any electrical conductor or system in which there is a flow of current, there is a certain amount of energy continually being lost or converted into forms not readily returned to the circuit as electrical energy. As far as is known at present, this dissipation of energy may take one of two forms. There may be an evolution of heat or radiation of energy into space. Such energy dissipation is attributed to a property of electrical conductors or systems termed "resistance."

When dealing with continuous currents, the resistance of a conductor or network R is adequately defined by *Ohm's law*,

$$E = iR \qquad (1)$$

where E is the voltage drop across the conductor or network and i is the current through it. This assumes no back emf due to polarization or other causes. In this case the dissipation of energy takes place entirely in the form of heat generation, and the rate at which electrical energy is thus converted into heat is given by *Joule's law*,

$$P = i^2R \qquad (2)$$

where P is the power or rate at which electrical energy is being dissipated in the form of heat, i is the continuous current in the circuit, and R is the resistance of the circuit.

Ohm's law is insufficient to define resistance in a-c circuits. It is found experimentally that the rate at which energy is lost in a circuit exceeds that which would be necessitated by the resistance of the circuit as determined by Ohm's law. This is because the electromagnetic and electrostatic fields around the circuit vary with time and introduce effects which increase the losses in the circuit. Among these effects may be enumerated the following major ones:

1. *Eddy-current* losses in conductors and other masses of metals in and near the circuit.
2. *Hysteresis* losses in magnetic materials.
3. *Dielectric* losses in the insulating mediums.
4. *Absorption* of energy by neighboring conductors or circuits by induction.
5. *Radiation* of electromagnetic energy into space.
6. *Skin Effect.* Increase of conductor resistance due to nonuniform current density.

All these effects result in an increase in energy loss in the circuit over and above that given by Ohm's law. It therefore becomes necessary to introduce the concept of *a-c resistance* or *effective* resistance, which is defined by the more general Joulean relationship

$$P = i^2R \text{ effective} \qquad (3)$$

where P is the power loss in the circuit due to all causes and i is the effective current in the circuit. Ohm's law for continuous currents follows directly from this more general definition.

2. Units of Resistance. The practical unit of resistance is the *ohm* and is defined by Ohm's law when the voltage and current are unity in the practical system. In 1948, the "international" electrical units, which raised some minor questions as to

[1] International Resistance Co. The author wishes to acknowledge the assistance of Alexander L. Pugh, Jr., and Charles Wellard.

this "unity," were abandoned and a new system of measurement using *absolute* units was officially instituted. Now Ohm's law is correct by definition. Precision resistors are now marked "abs. ohms" to distinguish the standards of measurement. One mean international ohm equals 1.00049 absolute ohms. (Do not confuse with *abohm.*) Owing to the increasing use of resistors having resistances of the order of millions of ohms, the *megohm* unit is also employed. The megohm is equal to 10^6 ohms.

3. Specific Resistance. It is found experimentally that the resistance of an electrical conductor to continuous current is directly proportional to its length and inversely proportional to its cross section:

$$R = \rho \frac{l}{A} \tag{4}$$

The proportionality factor ρ is called the *specific resistance* of the conductor and is a function of the material of the conductor and temperature.

From this definition of specific resistance it is apparent that any number of units may be derived for specific resistance, depending upon the units chosen for l and A. The unit generally employed in practical engineering is *ohms per circular mil foot*, and is the resistance of a 1-ft length of the conductor having a section of 1 cir mil (diameter 1 mil, 0.001 in., for a circular conductor).

Therefore, the resistance of a piece of wire of circular cross section is equal to the ohms per circular mil foot of the metal, times the length in feet divided by the square of the diameter in mils.

4. Volume Resistivity. If, in the above definition, l and A are both unity in the same system of units, then ρ is the resistance between the opposite faces of a unit cube of the material and may be defined as the *volume resistivity* of the material. It should be noted that volume resistivity is not the resistance of any unit volume of the material but is specifically the resistance of unit volume measured between opposite faces whose areas are each unity.
FIG. 1. Simple series circuit.
FIG. 2. Parallel circuit.

With a knowledge of the dimensions of a conductor and its specific resistance the resistance of the conductor to d.c. may be computed from Eq. (4). Consistent units must be employed. The resistance thus computed will be correct at the temperature for which the specific resistance applies. To obtain the resistance of the conductor at any other temperature a correction must be applied.

5. Temperature Coefficient. The resistance of a conductor is a function not only of the material and dimensions of the conductor but also of its temperature. Within the temperature limits generally encountered in practice, the change in resistance due to temperature variation is directly proportional to the change in temperature:

$$R_{t2} = R_{t1}[1 + \alpha(t_2 - t_1)] \tag{5}$$

R_{t1} and R_{t2} are the conductor resistances at temperatures t_1 and t_2, respectively.

The proportionality factor α is defined as the *temperature coefficient of resistance* of the material and is the change in resistance of any material per ohm per degree rise in temperature. Sometimes α is multiplied by one million and the temperature coefficient of resistance is reported as ppm/1°C (parts per million per degree centigrade).

All conductors do not react alike to changes in temperature. Metals, for example, have a positive temperature coefficient. Some alloys, such as manganin and constantan, have practically zero temperature coefficient and are therefore used primarily for resistance standards.

A knowledge of the temperature coefficient of conductor materials enables one at times to make more accurate determinations of temperature change than is possible by thermometer measurements, especially in cases where parts to be measured are not readily accessible. Resistance determinations of the conductor are made at two temperatures and the temperature change is computed from Eq. (5).

6. Properties of Materials as Conductors.

Materials	Specific resistance, ohms/cir mil ft	Temperature coefficient α per °C
Pure metals:		
Silver	9.796	+0.0038
Copper	10.37	+0.0039
Gold	14.55	+0.0034
Aluminum	16.06	+0.00446
Tungsten	33.22	+0.0045
Iron (pure)	60.14	+0.0050
Nickel	60	+0.0050
Platinum	63.8	+0.0030
Alloys:		
"30" alloy, alloy 30 (Cu 97.75%, Ni 2.25%)	30.0	+0.0015
"60" alloy, Lohm (Cu 94%, Ni 6%)	60.0	+0.0008
"90" alloy, 95 alloy (Cu 89%, Ni 11%)	90	+0.00049
Hytemco (Ni 72%, Fe 28%)	120	+0.0045
180 alloy, Midohm (Cu 77%, Ni 23%)	180	+0.00018
Manganin (Cu 87%, Mn 13%)	290	±0.000015
Advance, alloy "45," Copel, Cupron, Constantan (Cu 57%, Ni 43%)	294	±0.00002
Nichrome V, alloy "A," Chromel "A," Tophet "A" (Ni 80%, Cr 20%)	650	+0.00011
Nichrome, alloy "C," Chromel "C," Tophet "C" (Ni 61%, Cr 15%, Fe 24%)	675	+0.00015
Radiohm (Fe 78.5%, Cr 16.5%, Al 5%)	800	+0.00007
"331" alloy, Karma, Evanohm (Ni, Cr, Al, and small trace of Fe)	800	±0.00002

7. Resistors in Series and Parallel. Simple and complex networks of resistors may be represented by an equivalent resistor expressed in terms of the individual resistances making up the network. The equivalent resistance of a number of resistors connected in series is equal to the sum of the individual resistances. Referring to Fig. 1,

$$E = iR_{\text{equiv}} = e_1 + e_2 + \cdots + e_n = R_1 i + R_2 i + \cdots + R_n i = i(R_1 + R_2 + \cdots + R_n)$$

$$\frac{E}{i} = R_{\text{equiv}} = (R_1 + R_2 + \cdots + R_n)$$

$$R_{\text{equiv}} = \sum_1^n R$$

The reciprocal of the equivalent resistance of a number of resistors connected in parallel is equal to the sum of the reciprocals of the individual resistances. Referring to Fig. 2,

$$i = i_1 + i_2 + \cdots + i_n = \frac{E}{R_1} + \frac{E}{R_2} + \cdots + \frac{E}{R_n}$$

$$\frac{i}{E} = \frac{1}{R_{\text{equiv}}} = \frac{1}{R_1} + \frac{1}{R_2} + \cdots + \frac{1}{R_n}$$

$$\frac{1}{R_{\text{equiv}}} = \sum_1^n \frac{1}{R}$$

5.0	2.043	13.5	5.033	100.0	35.61

It is frequently useful to know the largest diameter of wire of different materials that will give a ratio of R_f/R_0 of 1.01 for different frequencies. For a ratio of R_f/R_0 equal to 1.001, the diameters given in Sec. 10 should be multiplied by 0.55; and for R_f/R_0 equal to 1.1, the diameters should be multiplied by 1.78.

9. Skin Effect. The resistance of a conductor is a minimum when the current density is uniformly distributed over the cross section of the conductor. This condition occurs with d.c. The resistance increases for nonuniform distribution of current density over the cross section of the conductor. The latter condition exists in conductors carrying a.c. This is a result of the distribution of magnetic flux lines, outside and inside the conductor. If the conductor is assumed to be made up of a number of conducting elements in parallel, then the interior elements, being surrounded by more flux lines than the exterior, will have greater reactance and, therefore, the current in the interior elements will be less than that in the exterior elements. As a result, the current crowds toward the surface of the conductor, giving a nonuniform current density. This imperfect penetration of current in a conductor, resulting in an increase in resistance, is termed "skin effect."

This effect is important in high-Q circuits but is seldom significant in the usual application of high-resistance alloys as small-diameter wires.

Skin effect in a conductor is a function of the following factor:

$$t\sqrt{\frac{\mu f}{\rho}} \qquad (6)$$

where t = thickness of the conductor
f = frequency of current
μ = permeability of the conductor
ρ = specific resistance of the conductor, microhm-cm*

It is possible to compute accurately the h-f resistance of simple round cylindrical conductors from involved functions of the above factor. To facilitate these computations, tables have been prepared from which the ratio of h-f resistance R_f to d-c resistance R_0 may be quickly determined. From this factor and the easily measured d-c resistance, the h-f resistance may be computed.

The table in Sec. 8 gives the values of R_f/R_0 for different values of the factor

$$x = \pi d\sqrt{\frac{2\mu f}{\rho}}\sqrt{\frac{1}{1{,}000}}$$

where d is the diameter of the wire in centimeters, ρ is the volume resistivity in microhm-centimeters (1.724 at 10°C for copper), x may be computed for any particular case, and R_0 may be measured at d.c. or computed.

11. Reduction of Skin Effect. In view of the tendency of the current to crowd to the surface of the conductor at high frequencies, the remedies that have been found practical in effecting an improvement in the resistance ratio R_f/R_0 have been those in which the conductor has been designed so that it presents a thin skin to the current flow; *i.e.*, the conductor should be a thin skin rather than a solid conductor of large cross section of which only a small part is used at high frequencies. These are:

1. *Use of Flat Copper Strip.* While skin effect is present, for the same cross-sectional area a flat strip gives a lower resistance ratio than do round conductors.

* Microhms per centimeter length of a conductor having a cross section of 1 sq cm.

10. Maximum Diameter of Wires for H-f Resistance Ratio of 1.01.

2. *Use of Tubular Conductors.* The resistance of the internal portion of the conductor is affected much more by increase in frequency than the outer portion; therefore, the resistance of thin tubular conductors changes less with increase in frequency than does that of solid conductors.

3. *Use of Litzendraht.* According to Eq. (6), the smaller the diameter of the wire, the less the skin effect. Litzendraht is a braided cable made up of a large number of fine strands of wire. When certain precautions are taken, this braid shows a very much lower resistance ratio than does a solid copper wire of equal section. These precautions are:

a. Each strand must be thoroughly insulated from every other strand to avoid contact resistance.

b. Braiding must be such that each strand passes from the center to the outside of the conductor at regular intervals—a sort of transposition. This ensures that all strands are affected alike by the magnetic flux.

c. Each strand must be continuous.

GENERAL CONSTRUCTION OF RESISTORS

Basic elements in the construction of resistors are:

1. Base
2. Resistive element
3. Terminations
4. Protective cover

12. Base. Important characteristics of a base suitable for the manufacture of resistors are:

1. It should have high insulation resistance at room and elevated temperatures.
2. It should not have much ionizable content; otherwise ionic conduction will result with consequent electrolysis and corrosive effect.
3. It should have high mechanical strength.
4. It should have low moisture absorption; otherwise it should be protected against moisture.
5. It should be capable of withstanding high thermal shock.
6. Its coefficient of thermal expansion should approximate as closely as possible that of the resistance element and protective coating of the resistor.
7. It should have low h-f losses when the resistor is intended for high frequencies.

The more common choices for resistor bases are:

1. Ceramic
2. Glass
3. Plastics

Ceramics. Generally used for winding forms for precision and power wire-wound resistors. They are used for the base of high-frequency and high-voltage composition resistors, for pyrolitically deposited carbon, boron-carbon, and for metal film resistors. The ceramic properties, which vary with composition and with details of their manufacture, influence the electrical properties of the resistor.

Glass. Used as the insulating base in one of the types of fixed composition resistors. It is used as the base for conductive-oxide types of resistors, and for the base for some metallic-film types. In the form of fiber glass, it is formed into a hard, somewhat flexible bundle and used as the base for some wire-wound resistors. Glass offers the same general advantages as ceramic; it has a smoother surface but is more subject to damage by shock unless reinforced by means such as molding.

Plastics. Used as the base in composition variable resistors. Plastics or fiber is used for the base of many wire-wound resistors of the variable and the molded types and also precision wire-wound resistors. Plastics may not be operated at as high temperatures as ceramics or glass but they are not so brittle and may be die-cut and formed readily.

13. Resistive Element. The more common types of material used for the resistive element are:

1. Metal alloys (wire)
2. Carbon and graphite, usually with binders
3. Pyrolitically deposited films
4. Metallic films
5. Conductive oxides

14. Metal Alloys. The resistive properties of the more common metals and alloys used for resistors are given in Sec. 6. These properties are for bulk materials and do not hold if a dimension of the resistor element is the order of the mean free path of the electrons (see Sec. 17). Generally, alloys have higher specific resistance and lower temperature coefficients of resistance than pure metals. For these reasons, alloys are generally used for wire-wound resistors.

Three classes of wire, which may be round or flat, are generally used:

Nickel-Copper. Some of the more commonly known trade names are Advance, Constantan, Cupron, Midohm, and 30 Alloy. The nickel-copper alloys are made to cover a wide range of specific resistivities, which makes it possible to make very low resistance values without resorting to excessively large wire and resistor sizes. The temperature coefficient of these alloys, however, increases as the specific resistivity decreases. Constantan (Advance, Cupron) has a negligible temperature coefficient and is therefore widely used for precision resistors as well as in other types of resistors. It has a high thermal emf against copper and iron and is therefore widely used in thermocouples.

Nickel-Chromium. Commonly known by the trade names of Nichrome, Tophet, and Chromel. This class of alloys has a very low temperature coefficient and high specific resistance. It is made in two formulations: one iron-free, the other with a substantial percentage of iron.

Nickel-Chromium-Aluminum. Commonly known by the trade names of 331 Alloy, Evanohm, and Karma. This class of alloys has a very low temperature coefficient and the highest specific resistance of those commercially useful in resistors.

Alloy wires are made in sizes as low as 0.0005 in. in diameter. However, in resistor design there is usually a limit placed on the minimum allowable size. This is usually set at 0.001 in., the object being to reduce the possibility of failure due to corrosion and mechanical weakness. Where nickel-chromium alloy is used, it is sometimes recommended that the iron-free wire be used for wire sizes smaller than 0.002 in.

15. Carbon and Graphite. These conductors are used usually with binders to form the resistance element in the so-called composition-type resistors, both fixed and variable. The term *composition-type resistor* is employed to cover that group of resistors in which a conductor is mixed with a binder in definite proportions and suitably treated to produce a resistor material. The physical form it takes may be a solid body or a film. By and large, these resistors, whether of the solid-body or film type, are made in the same general way, although there are wide variations in materials, formulations, details of manufacturing procedure, etc. Resistor elements of this class are made by preparing a homogeneous mix of a conductor, generally graphite or carbon or both, with a resinous binder and sometimes a filler. In the case of the solid resistor, the binder is a resinous molding powder; in the case of the film resistor, the resin is in the form of a varnish. In both cases a curing operation is essential to harden the mass or film. The mixtures have infinite or very high resistance prior to the final polymerizing operation. This operation involving temperature, pressure, or both shrinks and fuses the resistive composition into a tough hard body or film. The resulting structure then consists of conducting particles held together by a dielectric binder. Resistance values are controlled by modifying the ratio of dielectric to conductor. The higher this ratio, the higher the resistance value. The conducting particles make contact with each other under the pressure that exists in the structure. Most of the resistivity of the device is a summation of the contact resistances between particles, so that whatever alters the contact pressure will affect the resistivity. Many of the performance characteristics of this class of resistor are a direct result of the structure of this device.

16. Pyrolitically Deposited Films. These resistive elements are made by decomposing hydrocarbons or other materials at very high temperatures to form conductive films upon a heat-resistant base, usually ceramic. The deposits are usually carbon but may be mixtures of carbon and other materials such as boron. The electrical properties are very good over a relatively narrow band of specific resistance; therefore the higher values are usually made by helixing (frequently called *spiraling*) the resistance film to the desired resistance values.

17. Metallic Films. These resistive elements are made by the decomposition of metallic compounds at high temperature forming metallic films, or by the evaporation or sputtering of metals upon a base under vacuum. They may be made from noble metals, alloys, or pure metals. These films are usually made very thin and it has been found that thin films have electrical properties that differ from those of the bulk material from which they are made. The specific resistance is much higher and the temperature coefficient of resistance varies from plus to minus, depending upon the material, the film thickness, and other factors. By proper selection of the materials, thickness of film, methods of deposition, and helixing, resistors of a wide range of resistance values are made that have temperature coefficients (T.C.) within 25 ppm per °C of any desired value between plus or minus 200 ppm (the mean value of T.C. can be more positive or negative on special orders). The films are very stable with time, with both low and high temperature, and withstand moisture and abrasion.

18. Conductive Oxide. Conductive-oxide resistive elements are made by fusing certain metallic oxides into the surface of glasses. The usual materials are combinations of tin and antimony oxides on pyrex glass which yield resistors of intermediate temperature coefficient of resistance and of intermediate resistance values.

19. Terminations. Terminations of resistors fall into four classes:

1. Wire leads
2. Lugs
3. Ferrules
4. Special

1. *Wire Leads, Radial or Axial.* Used on composition resistors, many lightweight resistors of the precision, low-power wire-wound, pyrolitic film, metallic-film, conductive-oxide types, and on some printed circuits. They are usually of solid tinned copper wire of a size suitable for the weight of the resistor. Some leads are coated with alloys that permit easy soldering even after long storage before assembly.

2. *Lug Terminals.* Used on variable resistors, power wire-wound resistors, precision resistors, and some others. They are usually of tinned alloys. Although most are supplied with holes to take wire some are "blind" for spot welding the resistors into the circuit.

3. *Ferrules.* Usually of a size to fit a standard cylindrical fuse clip and are made of alloys. They are usually used on high-power wire-wound resistors and for meter-multiplier resistors.

4. A few resistors are made with special terminals unique for their application such as for use in coaxial lines, and some, which are used as attenuators in wave guides, have no terminals.

20. Protective Cover. Most resistor elements are insulated and protected from damage during shipment, assembly, in use, and against adverse environment by a protective coating. The coatings may be nothing in the case of high-power water-cooled resistors where excellent heat transfer is essential but may be a thick plastic in some cases.

The usual protective coatings are:

1. Vitreous-enamel coatings
2. Cement coatings employing inorganic binders
3. Ceramic tube enclosures
4. Glass or ceramic tube enclosures, hermetically sealed
5. Cement coatings employing organic binders
6. Molded or cast plastic enclosures
7. Films

Coverings in the first four classifications are capable of withstanding temperatures in excess of 250°C without deterioration. They afford a high measure of protection against humidity. Exceptions to this statement are coverings employing sodium silicate (water-glass) binders which are highly hygroscopic and therefore unsuitable where resistance to humidity is an important factor.

The hermetically sealed tube enclosure affords the maximum protection against humidity. Such resistors are capable of standing severe thermal shock and numerous alternate immersions in salt water solution at 0 and 100°C, a requirement often specified by the U.S. Navy.

Coverings in the fifth classification are capable of withstanding temperatures up to about 175°C, varying with the nature of the binder. Resinous binders in general stand lower temperatures than asphaltic binders. They are, however, superior to the high-temperature coatings in their moisture-resistant properties. Silicone resin binders are capable of withstanding temperatures as high as 200°C and afford a high measure of protection against humidity.

Coverings of molded or cast plastic are capable of withstanding temperatures from 100 to 160°C, depending upon the nature of the molding material used. The ordinary general-purpose molding materials with wood-flour base are good at the lower temperatures, whereas the asbestos and mica-filled materials are good at the higher temperatures.

Coverings of the last classification are of one or more films of appropriate varnishes sometimes filled with a pigment to improve abrasion resistance. When carefully selected, these films provide some protection against humidity and mechanical damage.

RESISTOR RATINGS

21. Power Rating of Resistors. The power rating is primarily determined by the power that the resistor can dissipate continuously for an unlimited time without exceeding a permissible maximum temperature and without exceeding arbitrarily chosen performance limits. This limits the permissible temperature rise, which varies for different classes of resistors. The temperature rise is measured from a specified ambient temperature. Ambient temperature is defined as the temperature of the surrounding air.

22. Temperature Rise of Resistors. The temperature rise of resistors varies with the design, cooling, and power load. The temperature rise varies somewhat with different makes of resistors owing to differences in coating materials such as heat conductivity, texture, and color.

The 100 per cent rating is based upon the specified maximum temperature rise in free air. Resistors made to the same specifications have similar temperature rises, independent of resistance, when the rises for the same powers are compared. For this reason, typical temperature-rise curves, as given in later sections, can be used with reasonable accuracy in the design of equipment.

23. Power Derating. Nominal power ratings are based on specified good ventilation, which is seldom encountered in practice. The actual load at which resistors may be used safely is therefore usually less than the nominal rating. For example, in the case of high-power resistors nominally rated on the basis of 250°C rise from a 25°C ambient temperature, it is generally recommended that when used in confined space the loads be reduced to one-fourth to one-half nominal rating, resulting in temperature rises of 80 to 160°C. In practice, even these temperature rises may be excessive because of the proximity of the resistors to other parts that may not be subjected to elevated temperature, or to fire hazard, underwriters' requirements, etc. The specific application therefore limits the practical use of a resistor rather than the nominal rating.

In practice, the above considerations are taken into account by "derating" resistors. If a resistor is used at its nominal rating at an ambient temperature greater than its reference ambient, the maximum permissible temperature will be exceeded. To avoid

this, the temperature rise must be limited by the use of power low enough to compensate for the increased ambient. This is done by means of derating curves for each class of resistor showing ambient temperature vs. permissible operating load. This principle of derating applies to all classes of resistors. Every class of resistor can have such a derating curve computed from its rating and temperature-rise curve. Figure 3 shows a typical derating curve for fixed composition resistors. For derating curves applicable to specific types of resistors, see the appropriate sections. Derating curves of other resistors may be secured from the appropriate EIA or government specifications (see Sec. 24) or from the various manufacturers.
FIG. 3. Typical power derating curve for fixed composition resistors.

FIXED LOW-POWER RESISTORS

The types available include composition and wire-wound types. Each type has unique properties and limitations. These resistors have power ratings up to 2 watts. They are small, up to 1¾ in. long and up to 11/32 in. in diameter. Most are made with axial leads, 1½ in. long, of tinned copper wire of 18 gage or less diameter. The power ratings are usually 1/10, ¼, ½, 1, and 2 watts with maximum voltage ratings of 500 volts or less, depending upon power rating. More resistors of this type are used than all other types combined.

24. Wire-wound Low-power Resistors. The wire-wound types are available from 0.24 to 8,200 ohms but depend upon size. These units dissipate ½ to 1 watt per sq in. of surface. There are two general styles: (1) flexible resistors and (2) plastic-insulated resistors. Both have a core of either cord or glass fiber. The former has a textile or glass-fiber covering; the latter is molded in plastic. They are equipped with wire leads making them very convenient for "point-to-point" wiring in circuits, eliminating the necessity for special fittings for mounting. The flexible resistors with glass-fiber cores and coverings are capable of much higher ratings. The plastic-molded style has become standardized in the radio industry.

The wire-wound types are available in lower resistance values and have lower changes with applied voltage and lower noise levels than the composition types. The inductance and distributed capacitance are slightly greater and more variable, resistor to resistor, than the composition type. They are used extensively where

Table 1. Wire-wound Resistors with Plastic Insulation

Rating, watts based on 40°C ambient	Size, in.		Min resistance, ohms	Approx inductance, μh	Max resistance (JAN-R-184), ohms	Approx inductance, μh	Max resistance (standard), ohms	Approx inductance, μh
	Diam	Length						
½	3/16	5/8	0.24	0.087	470	0.6	870	2.5
1	¼	1¼	0.47	0.17	2,200	8.0	5,100	33
2	5/16	1¾	1.0	0.35	3,300	13	8,200	56

inexpensive, small, low-power resistors with good stability are required as, for example, in audio circuits, particularly with cathode follower, vibrator circuits, telephone circuits, radio, TV, etc.

Table 1 gives typical information about this class of resistor. The military specification covering this class is JAN-R-184; the industry specification is EIA REC-117.

Power Derating. The insulated wire-wound resistors of this class are derated for high ambient temperatures as shown in Fig. 4.

Color Code. The color code for resistance value and resistance tolerance is the same as described in Sec. 34 for composition resistors except that the first, or A, band is twice as wide as the other bands. The wide A band identifies the resistor as of wire-wound construction.

Standard Resistance Values. The standard resistance values per decade are the same as described in Sec. 35 for composition resistors.

FIG. 4. Power derating curve for molded wire-wound resistors (JAN-R-184 and EIA REC-117).

25. Composition Resistors. The composition-type resistor has attained a wide popularity in the manufacture of radio and allied products because of the following advantages: (1) flexibility in resistance—it may be made in any values from 10 ohms up to 100 megohms; (2) compactness—its physical dimensions are small for any resistance, and they may be made in sizes as small as 0.067 in. in diameter by 0.140 in. long.

Numerous styles of these resistors have been produced, but they take two general forms:

1. *Solid-body Resistors.* In this style the resistor material is extruded, pressed, or molded into its final physical form, which generally is a solid rod. After this it may be subjected to some form of heat-treatment. The so-called *carbon* resistor is an example of this style. It is produced both as an uninsulated resistor (as described) and as an insulated resistor with an outside molded insulating covering. Wire leads are used as terminals.
2. *Filament-coated Resistors.* Here a conducting coat or film is baked on the surface of a continuous glass filament or other form. In the case of the glass filament this is completely enclosed in an insulating housing. The so-called *insulated-filament* resistors are examples of this style. Wire leads are used as terminals.

The insulated type of resistor, in which the resistor element is molded in a plastic covering, is used almost universally and may be considered standard in the industry.

Table 2 gives typical information about this class of resistor. The military specification covering this class is MIL-R-11B. The industry specification, EIA RS 172, includes more sizes and classes.

Table 2. Insulated Composition Resistors

Power rating, watts (70°C ambient)	Max diam of resistor, in.	Max over-all length of resistors, in.	Max rated voltage, volts, d-c or rms
1/10	0.075	0.160	150
1/4	3/32	3/8	250
1/2	3/16	3/8	350
1	1/4	3/4	500
2	5/16	1 5/16	500

Composition resistors possess properties differing from those of metallic resistors. The most important, possessed by all styles in varying degree, are as follows:

26. Voltage Characteristics. The resistance is not independent of the applied voltage and decreases with increasing voltage. This characteristic is measured by a fac-

tor called *voltage coefficient* defined as
$$\text{Voltage coefficient} = 100 \frac{R_1 - R_2}{R_2} \times \frac{1}{E_1 - E_2}$$

where E_1 = rated continuous working voltage (usually applied for 0.1 sec at 10-sec intervals to avoid measuring the change due to temperature rise)
E_2 = 0.1 rated continuous working voltage
R_1 = resistance at rated continuous working voltage
R_2 = resistance at 0.1 rated continuous working voltage

The voltage coefficient is a function of

1. Composition of resistance mix.
2. Resistance value. For a given type of composition or mix and size of resistor, the coefficient decreases with decreasing resistance value.
3. Length of resistor. For a given composition and resistance value, the coefficient decreases with increasing length.

These facts are generally true of all types of composition resistors and are illustrated in Fig. 5, taken on resistors of two different lengths made with two resistance-material formulas. The reason for this behavior will be clear from the following: Lower resistance values for a given composition imply less insulating material in the
FIG. 5. Voltage characteristics of composition resistors.

mix. Greater length of resistor for a given value implies lower resistance per unit length of resistor and, therefore, less insulating material. The variation required in each of these factors to produce minimum voltage coefficient is in the direction to reduce the amount of the dielectric required in the mix.

The explanation is to be found largely in the observed relationship between the contact resistance of carbon particles and the voltage across contacts. The contact resistance between two carbon particles is an inverse function of voltage. Since most of the resistance resides in the contacts, anything that reduces the voltage across the contact of conducting particles will reduce the voltage coefficient. Increasing the number of conducting particles is the equivalent of reducing the amount of dielectric in the resistor, which is the condition for minimum voltage coefficient.

27. High-frequency Characteristics—Boella Effect. Unlike wire-wound resistors, which generally show a slight increase in resistance with frequency (skin effect), the composition-type resistor shows a pronounced fall-off in apparent a-c resistance from its d-c value with increasing frequency. This is particularly true of high resistance values. This effect, known as the "Boella effect" after its discoverer in Italy, was further investigated in England, where G. W. O. Howe proposed a theory explaining this behavior. He assumed that the resistor simulated a transmission line of half the length of the resistor, with uniformly distributed resistance and capacitance (see Fig. 6). He derived a universal relationship between R_f/R_0 and fR_0, in which the

ratio of R_f/R_0 is constant for equal products of R_0 and f. (R_f is the apparent h-f resistance at frequency f; R_0 equals the d-c resistance.) The fall-off in resistance value with increasing frequency is, therefore, due primarily to the shunting effect of the distributed capacitance in the resistor. Many observations confirm this theory generally, although Salzburg and Miller[1] show considerable departure at frequencies above 200 Mc. This subject was studied by R. F. Field. In an unpublished paper, he introduced the additional consideration of dielectric loss in the distributed and lumped capacitances in Howe's artificial line, which would increase still further the fall-off in apparent a-c resistance. The Boella effect in composition resistors of all types is a direct result of the resistor structure. Large numbers of conducting particles interspersed with a large amount of dielectric produce capacitances and their concomitant dielectric losses, which act as shunts at high frequencies.

FIG. 6. (*a*) Composition resistor of length L represented with lumped parameters. (*b*) Representation of (*a*) as transmission line having a length $L/2$ with uniformly distributed R and C.

28. Conditions for Good H-f Characteristics. On the basis of this analysis two important conditions follow for optimum h-f characteristics:

1. *Minimum dielectric* in the resistor mass and surrounding it. The dielectric constant and loss factors should be minimum.
2. *Geometry of Resistor.* As a direct result of this condition, the geometry of the resistor influences the h-f characteristics. Consider two resistors of equal length, one having twice the cross section of the other. For a given resistance value, the smaller unit would require resistance material with the lower specific resistivity. This means less dielectric, resulting in better frequency characteristics. The condition for minimum dielectric is therefore minimum cross section of resistor. Similarly, if the areas of both resistors are constant, the condition for minimum dielectric is maximum length. For best h-f characteristics, the ratio of area to length of the resistor should be a minimum.

The filament-type resistor most nearly meets both requirements established for minimum Boella effect. Its cross section is extremely small since it is a film. (Film thicknesses in commercial practice vary from 0.0002 to 0.001 in.) The film volume also being small, the dielectric mass is very low. Extensive tests of frequency characteristics of composition resistors have recently been made.[2] Curves from these data are shown in Figs. 7 and 8.

The reduction of resistance with increase of frequency of the electric signal is greater with the solid-body type. Most of the other properties are closely the same for the two types.

29. Resistor Noise Characteristics. Composition resistors all show, in varying degree, the presence of microphonic noise. The degree of noise is a function of the voltage, size of the resistor, resistance value, and the nature of the materials used. In general, for a given set of materials in the resistor, the noise level increases with increasing voltage, increasing resistance, and decreasing size.

It is interesting to note that the pattern of factors influencing noise is similar to that influencing the voltage coefficient and h-f characteristics of composition resistors.

[1] *RCA Rev.*, April, 1939.
[2] Interim Report, Part II, "Service Facilities and Materials for Performance Evaluation of Existing Types of Fixed Resistors in Ultra High Frequency Spectrum," Report 19A, Signal Corps Contract No. W 36-039-SC-44526.
Christensen and Pearson[1] reported that they failed to detect any noise in a solid carbon filament other than that due to thermal agitation. As a result, they concluded that most of the noise in carbon-composition resistors came from the contacts between carbon particles and that this was a function of voltage. They demonstrated that increasing the number of contacts would decrease the over-all noise. Empirical results with solid and film types of composition resistors confirm their conclusions.
FIG. 7. Frequency characteristic of thin-film vs. solid-slug types of ½-watt resistors.
FIG. 8. Composition-resistor frequency characteristics.

In the type of resistor under discussion, resistance is increased by adding dielectric binder. This is equivalent to reducing the contact density or the number of contacts per unit volume and increasing the resistance of the contacts. For a given current through the resistor or a given power in the resistor, this results in greater voltage drop across each contact, which produces greater noise. As in the h-f and voltage characteristic the condition for minimum noise is minimum dielectric in the resistor.

Noise is difficult to measure quantitatively and is not now a specified characteristic of resistors. Most composition-resistor manufacturers are reducing the noise level of their resistors, and most are so low that the microphonic noise cannot be detected in any but highly specialized amplifiers.

30. Humidity Characteristics. Although the general effect of humidity on resistors is to reduce resistance value because of resultant leakage, its effect on composition resistors is the opposite: resistance increases. This is because moisture causes expan-

[1] *Bell System Tech. J.*, April, 1936.

sion of the resistor binder material and separation of the conducting particles, with resulting increase in resistance value. This effect may be reduced by proper choice of materials and by suitable treatment of the resistor.

31. Temperature Characteristics of Composition Resistors. The T.C. of composition resistors is not a constant factor. It varies with resistance value, and for a given resistance it varies with temperature. It may even change sign at some point on the temperature scale.

This anomalous behavior is due to the peculiar structure of the resistor. A composition resistor is one in which the conductor (graphite, carbon, or other material), which may have negative and/or positive coefficients, is mixed in varying proportions with insulation. In addition, there is an insulating supporting base for the film-type
FIG. 9. Resistance-temperature characteristic, ½ watt, ⅛ by ⅜ in., composition resistor, Curve 1, 10 megohms; curve 2, 0.27 megohm; curve 3, 10,000 ohms; curve 4, 1,000 ohms.
FIG. 10. Resistance-temperature characteristic, ½ watt, ⅛ by ⅜ in., solid composition resistors. Curve 1, 1,000 ohms; curve 2, 10,000 ohms; curve 3, 0.100 megohm; curve 4, 1.00 megohm; curve 5, 10.0 megohms.

resistor. All these components react differently to temperature changes. Stresses are set up by even small differences in coefficient of expansion between these various components. Also, contraction and expansion may affect the contact pressure between conducting particles nonlinearly for the same temperature increment at different temperatures. The T.C. of the conducting material itself—graphite, carbon, or other material—is not the dominant factor in establishing the temperature characteristic of the resistor. Rather it is the result of all the stresses set up by differential expansion, which affects the contact pressure between conducting particles, and this pressure determines the ultimate resistance and therefore the T.C. As a result, it is necessary to speak of temperature characteristics over a wide range of temperatures rather than to cite a constant T.C.

Figures 9 and 10 show typical temperature characteristics of two types of composition resistors for different values and over a wide range of temperatures.

32. Power Rating Composition-type Resistors. The rating of composition-type resistors is complicated by many variables. The T.C. being large, it is possible for a resistance change to become quite appreciable before a temperature limitation is exceeded. Furthermore, with the higher resistances, such as 0.27 megohm and higher, in which the power dissipation may be very low, the voltage characteristics may be a determining factor instead of the load-carrying characteristic. Also, it is possible that the insulating materials used in and around the resistor may have some influence on the rating. It is therefore customary to rate this type of unit on the

basis of the maximum load it can carry, or the maximum voltage that can be applied to it for a long time, without exceeding prescribed resistance changes. The prescribed changes generally accepted are 6 per cent for intermittent rated-load operation and 3 per cent for 625 per cent of rated load for 5 sec.

FIG. 11. Power derating curve for fixed composition resistors.

33. Power Derating Composition Resistors. When composition resistors are used at ambient temperatures exceeding 70°C, the permissible maximum power which may be applied is shown by the derating in Fig. 11.

34. Color Code. The resistance value and tolerance of both composition and wire-wound fixed low-power resistors are indicated by color bands. Such identification simplifies assembly of these units and helps in servicing. There is complete agreement among the various standards for color coding these resistors, and all manufacturers follow the standards.

Fixed low-power resistors with axial leads have their nominal resistance values indicated by bands of color around the body of the resistor, in accordance with the following system:

Band A indicates the first significant figure of the resistance value. If its width is the same as the other band it is a composition resistor. If its width is twice as wide as the other bands it is a wire-wound resistor.

FIG. 12

FIG. 13

FIG. 12. Fixed composition resistor with axial leads.
FIG. 13. Fixed wire-wound resistor (note band *A* is twice as wide as bands *B* and *C*).

Band B indicates the second significant figure of the resistance value.
Band C indicates the decimal multiplier.
Band D, if any, indicates the tolerance limits about the nominal resistance value.

The color code and examples are given below:

Color	Significant figure	Decimal multipliers: Power of 10	Decimal multipliers: Multiplying value	Tolerance, %
Black	0	10^0	1	
Brown	1	10^1	10	
Red	2	10^2	100	
Orange	3	10^3	1,000	
Yellow	4	10^4	10,000	
Green	5	10^5	100,000	
Blue	6	10^6	1,000,000	
Violet	7	10^7	10,000,000	
Gray	8	10^8	100,000,000	
White	9	10^9	1,000,000,000	
Gold	..	10^{-1}	0.1	± 5
Silver	..	10^{-2}	0.01	± 10
No color	..	....	....	± 20

Examples illustrating the standard are as follows:

Ohms	A	B	C
10	Brown 1	Black 0	Black, no cipher
220	Red 2	Red 2	Brown, one cipher
3,300	Orange 3	Orange 3	Red, two ciphers
4,700	Yellow 4	Violet 7	Red, two ciphers
68,000	Blue 6	Gray 8	Orange, three ciphers
150,000	Brown 1	Green 5	Yellow, four ciphers

35. Standard Resistance Values (Preferred Numbers). The industry has adopted the standard resistance values in accordance with a preferred-number series. These values have been adopted universally for fixed low-power resistors. This series of values, appropriately rounded to two significant figures, is defined for each tolerance band as follows:

Although EIA Standard GEN 102 and Military Standard MS-91374 are defined for somewhat narrower bands of resistance values, they are used by industry in the band of 0.1 ohm to 100,000 megohms.

1. For tolerance of ± 5 per cent, a series of values in which successive values are related by the multiplying factor $\sqrt[24]{10}$, *i.e.*, 1.10 approximately
2. For tolerance of ± 10 per cent, a series of values in which successive values are related by the multiplying factor $\sqrt[12]{10}$, *i.e.*, 1.21 approximately
3. For tolerance of ± 20 per cent, a series of values in which the successive values are related by the multiplying factor $\sqrt[6]{10}$, *i.e.*, 1.46 approximately

The table below gives the basic decade of standard preferred resistance values for each of the three standard tolerances.

Standard Preferred Resistance Values

Tolerances available, per cent					
5	10	20	5	10	20
1.0	1.0	1.0	3.3	3.3	3.3
1.1			3.6		
1.2	1.2		3.9	3.9	
1.3			4.3		
1.5	1.5	1.5	4.7	4.7	4.7
1.6			5.1		
1.8	1.8		5.6	5.6	
2.0			6.2		
2.2	2.2	2.2	6.8	6.8	6.8
2.4			7.5		
2.7	2.7		8.2	8.2	
3.0			9.1		

FIXED PRECISION RESISTORS

There are two classes of precision resistors, depending upon the nature of the conductor, namely, wire and film. Wire-wound precision resistors are usually used where low tolerance, 0.1 to 1 per cent, and high stability are required. Film types are used where the tolerances are of the order of ½ or 1 per cent and some sacrifice in stability

can be tolerated. For h-f applications, film types are almost always better because of their very small reactive components. Wire-wound precision resistors are considerably more expensive than precision film types, and thus their selection must usually be justified on a tolerance, stability, and economy basis.

36. Precision Wire-wound Resistors. These resistors are wound on forms, usually ceramic or plastic such as epoxy, having an even number of sections separated by thin barriers. The winding consists of enameled alloy resistance wire, multiple-layer-wound, adjacent sections being wound in opposite directions. The minimum wire size recommended is 0.001 in. over the enamel. The winding is usually continuous, although as many as four breaks, welded or brazed, are permitted in practice. Although adjacent sections are wound in opposite directions, the resistors are not noninductive. In audio circuits they do, however, help reduce inductive pickup. The wound resistor is then covered by an insulating coating to protect it against humidity. For less critical applications, the coating may be wax, varnish, or any other suitable material. For severe environmental conditions such as high humidity, resistors hermetically sealed in a ceramic container or encapsulated in epoxy resin or molded are preferred. Terminals used are wire leads or soldering lugs.

Precision resistors are available in a number of sizes and ranges as shown in Table 3. Although this table is not all-inclusive, it serves to indicate the general types that can be obtained. Table 4 lists the more common resistance alloys and their characteristics.

Table 3. Fixed Precision Wire-wound Resistors

Military type numbers	RB15	RB17	RB18	RB19
Power rating, watts*	½	1	1¼	2
Max voltage rating	300	700	1,000	2,000
Resistance min, ohms	0.1	0.1	0.1	0.1
Max resistance (for military use), megohms	0.4	1	3	6
Resistance max (for commercial use), megohms	1.5	4	7.5	20
Number of pie sections	2	4	6	8
Dimensions, in.:				
Length	7/16	31/32	1¼	2 3/32
OD	11/16	21/32	¾	1

Military-type epoxy encapsulated or molded, specification MIL-R-93A, commercial type, varnish coated.

* Power ratings based on 85°C ambient for military use, 65°C ambient for commercial use.

Table 4. Resistance-alloy Characteristics

Symbol	K	E	N	J
Alloy	Copper-nickel	High-resistivity nickel chrome	Nickel chrome iron	Nickel chrome
Trade names	Alloy 45, Advance, Copel, Cupron	Evanohm, Karma	Alloy C, Chromel C, Nichrome, Tophet C	Alloy A, Chromel A, Tophet A, Nichrome V
Resistance, ohms per cir mil ft at 25°C	294	800	675	650
Temp. coefficient of resistance, ppm/°C from 0–100°C	±22	±22	170	130
Thermal emf to CU, μv/°C from 0–100°C	−43	+3	+2	+5

Rating-Derating. It will be noted from the tables that there are two ratings, power and maximum voltage. The power rating is applicable to all resistance values up to that requiring the maximum voltage. The voltage rating applies to higher resistance values.

Derating curves are usually supplied by each manufacturer for their product. Typical curves for the epoxy encapsulated units are shown in Fig. 14.

37. Precision Voltmeter Multipliers. The more common construction of this type of precision resistor consists of a number of individual precision resistors interconnected and encased in a glazed ceramic or glass tube. Metal ferrule terminals are applied to the ends of the tube and are hermetically sealed by soldering to metal bands bonded to the ceramic. Variations in these construction techniques are sometimes employed to accomplish the same over-all result. These are available in three standard sizes with resistance ranges as follows:

Military type	MFA	MFB	MFC
Length, in.	9 25/32	5 9/32	2 15/16
Ferrule diam, in.	19/64	19/64	13/16
Min resistance, megohms	3.5	1.0	0.5
Max resistance, megohms	12.0	6.0	1.2

These resistors have a current rating of 1.0 ma maximum and the voltage rating in kilovolts is equal numerically to the resistance expressed in megohms. Standard tolerances are 0.5 and 1 per cent, but 0.1 per cent is available on special order. The military specification is JAN-R-29.

38. Film Resistors. *Deposited Carbon and Boron Carbon.* Deposited-carbon and boron-carbon precision resistors will be treated together, for these two types have much in common.

The deposited-carbon resistor is a film resistor, differing from the composition type in that the resistance film contains no dielectric material—only carbon. This film is deposited on a ceramic tube or rod by pyrolysis, *i.e.*, the cracking of a hydrocarbon gas at elevated temperatures in the proximity of the heated ceramic form. Under suitable conditions, crystalline carbon deposits on the ceramic to form an extremely hard dense film. Terminals may be wire leads, lugs, or ferrules. To obtain high resistance values, a helical groove is cut in the carbon coating, resulting in a long resistance path.

The process for making boron-carbon films is essentially the same as for deposited carbon, with the addition of a boron-containing gas being introduced during the cracking phase. This has the effect of reducing the T.C. over a limited range of values.

FIG. 14. Power derating curve for high ambient temperatures.

These resistors are provided with protective covers which may be multiple varnish coatings, plastic molding, ceramic casing, or a hermetically sealed glass case evacuated or filled with an inert gas. These insulated types usually increase in cost in the order given. The varnished type provides the least protection against mechanical abuse and humidity. For high reliability and military applications, the molded and encased units are preferred. Tables 5 and 6 give the basic information for these resistors.

Temperature Coefficient. The T.C. envelopes of deposited and boron-carbon resistors are shown in Figs. 15 and 16. The envelope shows the spread one can expect on T.C. on a lot-to-lot basis from different manufacturers.

High-frequency Characteristics. One advantage these resistors offer over precision wire-wound units is their frequency characteristic. Figure 17 shows the approximate frequency characteristic for coated ½-watt resistors. Coated resistors are somewhat better in frequency response than the equivalent molded units.

Table 5. Coated Deposited-carbon and Boron-carbon Specifications

MIL style	Power rating at 40°C ambient, watts	Max voltage rating, volts d-c	Body dimensions		Resistance values, deposited carbon	
			L length, in.	*D* diam, in.	Min, ohms	Max, megohms
RN32	1/8	250	9/32	5/64	50	1

RN30	2	750	2 1/16	19/64	30	10

Table 6. Molded Deposited-carbon and Boron-carbon Specifications, Military Specification MIL-R-10509B

MIL style	Power rating at 70°C ambient, watts	Max voltage rating, volts d-c	Body dimensions		Resistance values, ohms			
					Deposited carbon		Boron carbon	
			L length, in.	*D* diam, in.	Min	Max	Min	max
RN60	1/8	250	13/32	1/8	50	1 megohm	50	100,000
RN65	1/4	300	5/8	3/16	20	2 megohms	20	100,000
RN70	1/2	350	23/32	1/4	10	5 megohms	10	100,000
RN75	1	500	1 1/8	13/32	10	10 megohms	20	0.237 megohm
RN80	2	750	2 1/4	13/32	15	20 megohms	30	1 megohm

Standard tolerance is ±1 per cent. Can be supplied to ±0.5 per cent tolerance.

Temperature Rise. Figure 19 shows typical surface-temperature-rise data for the five standard sizes of molded deposited-carbon resistors.

Derating. Typical derating curves for coated and molded styles are shown in Fig. 18.

39. New Developments. "Carbon Alloy" Film. Research indicates that the inclusion of additives to the hydrocarbon gas during the cracking process may alter the properties of the film substantially by increasing permissible operating temperature, decreasing moisture sensitivity, and extending resistance coverage. So-called "car-
FIG. 15. Temperature-coefficient spread for deposited-carbon resistors.

bon alloy" film resistors operate satisfactorily at ambients of 200°C, and can be made as high as thousands of megohms.

40. Metal-film Resistors. There are several different varieties of metal-film resistors. In general, they offer the advantages of the deposited-carbon resistors. Some types have the additional advantages of extremely low and controllable T.C. over the entire range of values, and suitability for high-temperature operation.
Fig. 16. Temperature-coefficient spread for boron-carbon resistors.
Fig. 17. Approximate frequency characteristics for ½-watt deposited-carbon resistor.

41. Evaporated Metal-film Resistors. These resistors are generally similar in physical appearance and dimensions to the deposited-carbon resistors. The resistance film is metallic and is deposited on a ceramic or glass form by evaporating a metal or alloy in vacuum. The metallic vapor condenses on the substrate to form a hard dense film. A helix is cut in the film, resulting in a long path and the desired resistance value. Terminations and protective covers are applied as with deposited-carbon resistors.
Fig. 18. Typical derating curves for coated and molded resistors.
Fig. 19. Surface temperature rise vs. load, molded deposited-carbon resistors.

General Specifications. Physical dimensions and ranges of resistance values are generally the same as those shown for deposited-carbon resistors in Tables 5 and 6. The military specification applicable to these resistors is also the same, MIL-R-10509B. While this specification calls for operation at 70°C, some manufacturers offer full-load operation in ambients as high as 125°C. At least one manufacturer offers all five molded sizes called for in the foregoing specification, with temperature coefficients as low as 0 ± 25 parts per million per degree centigrade. Standard tolerance is ±1 per cent, but these resistors are also available in tolerances of ±0.5 per cent and ±0.25 per cent.
FIG. 20. Derating curve for metal film resistors, two different manufacturers.

Rating-Derating. Although the military rating is based on 70°C ambient, some manufacturers claim ratings at higher ambients. Figure 20 shows derating curves for two different manufacturers.

Hermetically Sealed Resistors. When these resistors are sealed in glass envelopes by conventional methods and the envelope is filled with helium, the rating is increased substantially. Operation at ambients as high as 150 to 200°C at full rating and 250°C at one-third rating has been accomplished. Such resistors have stability equal to precision wire-wound resistors.

Controlled Temperature Coefficient. The most interesting characteristic of the evaporated-metal-film resistor is shown in the graph of Fig. 21. This shows the T.C. range available for a wide array of resistance values for the various sizes of resistors. The line to the left of the crosshatched area represents the properties of nonspiraled resistors and shows how the T.C. varies with the thickness of the evaporated film. The
FIG. 21. Range of temperature coefficient available for resistors of various sizes.
FIG. 22. Derating curve for conducting oxide-film resistors.

coefficient is positive for thick films; the magnitude decreases as film thickness decreases, crosses zero, and then turns negative for thin films. The point of zero T.C. is called the *crossover* point. This varies with the metal or alloy used. This phenomenon makes it possible to supply these resistors with controlled T.C. They can now be obtained on order to these T.C.s in parts per million per degree centigrade:

0 ± 50,	0 + 50,	0 − 50
0 ± 100,	0 + 100,	0 − 100
0 ± 150,		

42. Conducting Oxide-film Resistors. In this class of resistors, conducting oxides of tin and antimony are bonded at elevated temperatures to a glass rod or tube. The resistance element is then helixed to desired values. These are made, in general, to the same mechanical specifications as deposited-carbon and metal-film resistors.

Rating-Derating. For equivalent sizes and power rating of deposited-carbon and metal-film resistors, this type is rated by the manufacturer at 120°C ambient. The rating is doubled at 40°C ambient. This is shown in Fig. 22.

FIXED MEDIUM-POWER RESISTORS (WIRE-WOUND TO 20 WATTS)

These units dissipate between 2 and 4 watts per sq in. There are several different types in this class, the principal ones being:

43. Flat Wire-wound Medium Power. This type consists of wire wound on strips of fiber or laminated phenolic insulation to which lug terminals are attached at appropriate points. The strip is covered with phenolic either by molding or by other means. This assembly is then tightly enclosed in a sheet-metal punching with mounting holes, or a metal mounting strip is attached in intimate engagement with one side of the resistor, enabling the other side to be mounted flat against a metal chassis.

This design has many advantages. It is easy to mount. The metal enclosure, or mounting strip, and the chassis act as heat distributors and prevent excessive differences in temperature along the length of the unit. Use is made of the metal chassis and metal mounting to conduct heat away from the resistor. This makes possible higher power ratings for a given temperature rise. In effect this type of mounting approximately doubles the free-air rating of the resistor. For example, a resistor of this type, having a rating of 3.9 watts when suspended in free air, will have a rating of 7.4 watts when mounted on a steel plate 1 ft by 1 ft by 1/16 in.

They are used in the power range from 2 to 20 watts. Lengths vary from 2 to 6 in. Widths vary from 1/2 to 3/4 in. Terminals employed are generally soldering lugs.

44. Square-cross-section Medium-power Resistors. The resistance element consists of wire wound on a fiber-glass core assembled in a ceramic case of square cross
FIG. 23. Derating curve for resistors of square cross section of 5-, 7-, or 10-watt rating.
FIG. 24. Temperature rise vs. load for resistors of square cross section of 5-, 7-, or 10-watt rating.

section. The case is then filled with an inorganic cement which seals the resistor. The construction permits mounting against a flat metal panel for better heat conduction. It also permits magazining for automatic assembly to printed wired chassis. These resistors are supplied in 5 and 10 per cent tolerance. Typical dimensions and ratings are shown in the table at top of page 2-24. Figures 23 and 24 show typical derating and temperature rise for this class of resistor.

Power rating, watts	Dimensions		Resistance range, ohms
	Length, in.	Cross section, in.	
5	7/8	3/8 × 3/8	0.25– 3,300
7	1 3/8	3/8 × 3/8	0.5 – 9,000
10	1 7/8	3/8 × 3/8	5 –15,000

FIXED HIGH-POWER RESISTORS (10 TO 200 WATTS)

These resistors have the highest power ratings of the resistors normally used in electronic circuits. They dissipate 5 to 10 watts per sq in. of surface at 250°C rise from a 25°C ambient temperature when protected with inorganic materials. In the cases where higher powers are required, it is conventional to use several of these resistors in series.

45. High-power Wire-wound Resistors. These resistors are usually made by winding wire on ceramic forms and insulating and protecting them with inorganic and, for special applications, with organic materials. Many of the ceramic forms are circular in cross section but a "flat" style of elliptical cross section is also available for special or stack mounting. Most of these are protected with vitreous enamel or with cement. Some with circular cross section are hermetically sealed in tempered glass, some are made with many coats for protection against salt spray, and some are coated with an organic coating material for improved service in humid conditions but at reduced power ratings.

The terminals used on these resistors are wire leads, soldering lugs, or ferrules for mounting in fuse clips. Most manufacturers can supply L brackets with suitable insulating washers and through bolts for mounting these resistors. Some manufacturers also have Z brackets for mounting that do not require insulating washers and are less expensive but are more flexible.

These resistors are used for voltage dividers dissipating appreciable power, in grid circuits of high-power oscillators, and in a wide variety of circuits requiring high-power dissipation.

The most widely used power resistor is cylindrical in shape, and detailed specifications are given in military specification MIL-R-26B and industry specification EIA TR-132. The sizes, styles of terminals, power ratings, and ranges of resistance values are numerous. Typical information covering the ferrule-type resistor is given in Table 7.

Table 7. Standard Ferrule Types (JAN or MIL and EIA)

Type	Wattage	Max over-all length, in.	Body length, in.	Max shoulder diam, in.*	Fits form No. 1 std. clip fuse	Min ohms	Max ohms 0.0025 wire	Max ohms 0.00175 wire	Max ohms 0.0014 wire

* Body diameter is always less than shoulder diameter.

Most manufacturers offer many sizes that are not mentioned in these specifications. Examples of the range of sizes manufactured with lug-type terminals made by a manufacturer are given in Table 8. These resistors are available with taps and open sections on special orders.

46. Special High-power Wire-wound Resistors. *Flat Type.* This is a wire-wound resistor using a rather flat elliptical ceramic with a hole of rectangular cross section through which the mounting bracket, made of a good heat-conducting metal such as copper or aluminum, is passed. The advantage of this type is that the heat is conducted from the unit, by means of the metal mounting bracket, to the chassis on which it is mounted. This results in a more uniform temperature distribution along the length of the resistor. The mounting hardware enables these units to be stacked one on top of another and so provides some space saving. However, the power rating of each resistor is reduced when used in this way because of the heat radiation from one unit of the stack to the other. The reduction in rating to be expected is as shown in Table 9.

Adjustable Resistors. In many applications a fixed resistance value is required, but the exact value is not known. The adjustable resistor fills this need. This is a standard cylindrical power resistor with a cement or vitreous-enamel coating. A portion of the form along its entire length, usually ¼ in. wide, is left uncovered, leaving the wire exposed. This forms a track on which an adjustable terminal, which makes pressure contact on the wire, may be moved until the proper value is obtained, after which the terminal is locked in position. Such resistors are made to tolerances of ±10 per cent only.

Noninductive Type. Power wire-wound resistors of all styles can be wound noninductively by using the Ayrton-Perry winding, consisting of two windings in opposite directions, with both windings connected in parallel. This type of winding has not only low inherent inductance but low capacitance as well if wound with bare wire. The crossover turns reduce the distributed capacitance because the adjacent turns have very little potential difference between them. Typical inductance specifications for this type of resistance are shown below.

Resistance Value, Ohms	Max Residual Series Inductance, μh, Measured at 1-3 Mc
1-99	0.5
100-999	1.0
1,000 or higher	2.0

Because of the double winding it is necessary to wind the noninductive resistor with very large pitch. This materially limits the maximum value of resistance obtainable on a given form, as shown by the following examples.

Size of winding form		Max resistance value, ohms	
Diam, in.	Length, in.	Inductively wound	Noninductively wound
5/16	1¾	12,000	2,000
9/16	3	37,000	2,000
3/4	4½	90,000	5,000
1⅛	6¼	200,000	5,000

47. Power Rating of Wire-wound Resistors. In view of the low temperature coefficient of the resistance wires generally employed in wire-wound resistors, the resistance change with loads normally encountered is small. The power rating is, therefore, primarily determined by the power that the resistor can dissipate continuously for an unlimited time without exceeding the permissible maximum temperature and without deterioration. This limits the permissible temperature rise, which varies for different classes of resistors, as measured from a specified ambient temperature, usually 25 or 40°C.
FIG. 25. Temperature rise for power wire-wound resistors in free air, inorganic coatings.

48. Temperature Rise of High-power Wire-wound Resistors. Although the temperature rise varies somewhat with different makes of resistors owing to differences in coating materials such as texture or color, Fig. 25 is typical and shows the temperature rise to be expected at various loadings of these resistors wound on ceramic forms, with vitreous-enamel and cement coverings. The 100 per cent rating is based on manufacturers' rating of 250°C rise in open air. Temperature is measured at the center of the outer surface of the resistor, the resistor being in free air. The factors influencing this rating are:

1. Heat-resistant properties of protective covering.
2. Heat-resistant properties of core.
3. Use of intermediate taps. Taps reduce effective winding space, resulting in less active cooling surface and thus reducing the nominal rating. The extent of reduction depends upon the length of the resistor, being smaller for long units than for short ones. On short units 2 in. long, the rating may be reduced by as much as 15 to 20 per cent; on units 6 in. long the reduction may be 3 to 5 per cent.
4. Ventilation. See Secs. 23 and 50.
FIG. 26. Power wire-wound resistor derating curves.

49. Power Derating. In practice, the above considerations are taken into account by "derating" resistors. If a resistor is used at its nominal rating at an ambient temperature greater than its reference ambient, the maximum permissible temperature

will be exceeded. To avoid this, the r film on the inside of a glass tube. Water is fed
power low enough to compensate the y into the tube at a high velocity. It flows along
derating curves for each class of resisto ntact with the film and returns to its source.
operating load. This principle of dera vatts can be rated at 5 kw by such means. The
class of resistor can have such a derating cu
ture rise curve. Figure 26 shows typical ended. D-c operation destroys the resist-
tors having inorganic and organic coatings. r, etc., out of the water supply for they

FIXED HIGH-FREQUENCY RESISTORS

As commonly made, these resistors consist of ceramic tubes or rods with a resistive film deposited on the outer surface of the ceramic. This film may be a composition film described in Sec. 15 or any of the other film types described in Secs. 16 to 18. Conductive-film terminations are applied over the ends of the ceramic, to which leads, soldering lugs, or ferrule-type terminals are applied as required. For best h-f results the film should be continuous.

50. Composition-type H-f Resistors. Some of the characteristics are as follows:

1. The *temperature coefficient* varies with resistance value and varies from 0.005 per cent per °C for the minimum values indicated in Table 10 to 0.07 per cent per °C for the maximum values.
FIG. 27. Frequency characteristics of high-frequency resistors. (*a*) MPP resistor: *A*, 50 to 100 ohms; *B*, 1,000 ohms; *C*, 10,000 ohms; *D*, 0.1 megohm. (*b*) MPR resistor: *A*, 50 to 100 ohms; *B*, 1,000 ohms; *C*, 10,000 ohms.

2. The *voltage coefficient* also varies with resistance value and, between minimum and maximum resistance values, varies from approximately 0.002 to 0.03 per cent per volt per inch of length of resistance path. This limits the maximum voltage recommended.

3. Typical curves of the *frequency characteristics* are shown in Figs. 27 and 28 for different sizes and resistance values up to a frequency of 30 Mc for the higher-power units and 400 Mc for the low-power units.
...esistors are based on operation at an ...perature of 90°C for continuous opera... ...peration. Temperature rise curves for

this type resistor are shown in Fig. 29. If operated at higher ambients, it is necessary to derate in accordance with the derating curve in Fig. 30.

Increasing Power Ratings. This type of resistor, when operated in free air, is restricted to medium power ratings because of the temperature limitations of the materials used in the resistive film. Means for increasing the power rating are:

1. *Forced Air-draft Cooling.* The use of an air stream from a fan or blower can increase the rating from two to three times.

2. *Immersion in Oil.* This also has the effect of increasing the rating by a factor of 2 to 3.

Fig. 29. Type MP resistor; load-temperature rise in free air.
Fig. 30. Derating curve, type MP resistor.

3. *Water Cooling.* Extremely large increases in rating from 100 to 250 times the air rating can be obtained by appropriate methods of water cooling. This type of water-

cooled resistor is made with the resistor film on the inside of a glass tube. Water is fed through appropriate fittings tangentially into the tube at a high velocity. It flows along the resistor film in intimate thermal contact with the film and returns to its source. Resistors having a free air rating of 20 watts can be rated at 5 kw by such means. The rating depends upon the water flow.

Operation below 0.5 Mc is not recommended. D-c operation destroys the resistance film. Keep sand, grit, lumps of solder, etc., out of the water supply for they may cause early failure of the resistor. The power rating varies according to water flow, as shown in Fig. 31.

51. Carbon-alloy and Metallic-film H-f Resistors. Resistors employing films such as described in Secs. 38 and 40 have recently been introduced for h-f applications. The general construction is the same as for the composition type. The principal advantage of these films is their ability to operate at much higher temperatures than the composition films. The maximum operating temperatures of these types may reach as high as 225 to 250°C. In general, the power ratings of these resistors of a given size are approximately three to four times as great as those for composition resistors. As a result, these may be used for high-power h-f applications in place of power wire-wound resistors where their reactive component is too large. For metal-film resistors the T.C. is less than 0.03 per cent per °C and voltage coefficient is less than 0.001 per cent per volt. Table 10 gives a few typical sizes with pertinent information.
Fig. 31. Power rating of water-cooled resistors vs. flow of cooling water.

HIGH-VOLTAGE RESISTORS

The increasing use of high-voltage sources, as in radar, television, and X-ray equipment, introduced a requirement for resistors capable of handling high voltages at moderate power. Also, these resistors must be made to extremely high values, hundreds to thousands of megohms, so that the load on the high-voltage source may be low.

52. High-voltage Resistor Characteristics. High-voltage resistors are made by applying a resistance film on a ceramic tube as described in the previous section on

h-f resistors, except that the resistance path is a continuous spiral line. In this way a long resistance path can be obtained on a very short tube. For example, the resistance path on a tube 3 in. long and 9/16 in. in diameter can be made to have a linear length of 33 in. On the basis of a 300-volt-per-in. rating, such a resistor could be rated for 10,000 volts. The long resistance path also makes it possible to obtain very high resistance values more readily. For example, on the basis of 600 megohms per lineal in. of resistance path, which is readily obtainable with composition films, it is possible to obtain 20,000 megohms in this same resistor.

Various kinds of resistive films are used such as composition films, deposited-carbon films, conducting-oxide films. The most widely used thus far have been the composition films. These resistors are made in many sizes and ratings. Table 11 gives information on typical sizes of composition-film resistors as supplied by one manufacturer. The use of conducting-oxide films and carbon-alloy films makes it possible to operate these resistors at temperatures as high as 225 to 250°C.

Table 11. High-voltage Resistors

Types	Power rating, watts	Peak voltage rating	Dimensions, in.		Resistance, ohms		Resistance path length, in.

MVF	2	5,000	1 3/4	5/16	25,000	15,000	10
MVJ	5	10,000	3	9/16	0.2 megohm	20,000	33
MVO	30	50,000	10 1/2	1 1/8	2.0 megohms	20,000	330
MVR	90	100,000	18 1/2	2	7.0 megohms	20,000	1,050
MVM-6	...	30,000	6	5/16	75,000	1,500	77

The maximum allowable operating temperature is 100°C.

Voltage Coefficient. This varies somewhat with the manufacturer and may be important in some applications. It is a function of the voltage per unit length of the resistance path and of the resistance per unit length of the path.

The voltage coefficient of MV resistors shown in Table 11 varies from approximately −0.002/RPL to −0.03/RPL per cent per volt, depending upon resistance (RPL = resistance path length). The active length of the resistance path is given in Table 11 for calculation of approximate voltage coefficient.

Example: To determine a voltage coefficient for a low-range MVF resistor,

$$\frac{-0.002}{10} = -0.0002\,\%/\text{volt}$$

Temperature Coefficient. This is approximately −0.005 per cent per °C for low resistance values to −0.1 per cent per °C for high resistance values over the temperature range of −55 to +105°C.

VARIABLE RESISTORS

53. Variable Composition Resistors. In numerous applications high-valued variable resistors are required; *e.g.*, for controlling the sensitivity of a receiver by varying the bias on the r-f tubes a variable resistor up to 50,000 ohms maximum is commonly employed. For adjusting the audio signal level in a-v-c radio sets a variable resistor up to 2.5 megohms is not uncommon. From the point of view of cost, wire-wound resistors of this magnitude are prohibitive. Furthermore, it is frequently desirable to have a nonuniform rate of change of resistance with respect to angular rotation, which is very difficult to secure with wire-wound resistors. Therefore, carbon or graphitic types of variable resistors made to meet these requirements at reasonable cost are widely used.

There are two classes of this type of resistor:

1. *Film Type.* Such resistors generally consist of a resistive solution applied to some flat form, such as paper, plastic, or ceramic, and baked on. The resistor solution consists generally of carbon or graphite, or both, mixed in a resinous binder (varnish) or lacquer. This solution may be applied to the insulating base by spraying, rolling, printing, or other means of depositing a liquid. A rotating slider or some other form of contact travels over this resistive element and produces a continuous variation of resistance. Since the resistor is essentially painted on the form, its geometrical form may be varied by design. Also different concentrations of the resistor ink or paint may be employed at different positions of the resistor element. By the use of these two expedients, the resistor may be designed to give any resistance-rotation law desired.
2. *Solid Type.* The resistor element consists of carbon and graphite mixed with a resinous molding powder and molded in solid form to an insulating base. A rotating slider or other form of contact travels over this element and produces a continuous variation in resistance. By varying the ratio of conductor to binder along different positions of the resistor track, the resistor element may be made to follow different resistance-rotation laws.

In both types the resistance element is mounted on or embedded in an insulating base, and this assembly is enclosed in a metallic case. A line power switch is frequently assembled to the cover, which is operated by the shaft. Both types are made in resistance values up to 10 megohms. Standard tolerance for this type unit is 20 per cent, although they are also made to 10 per cent.

The mechanical characteristics are as follows:

1. *Size.* These controls are made in sizes varying from ½ to 1¼ in. in diameter. Standard sizes are ½, ¾, 15/16, 1⅛, and 1¼ in.
2. *Mounting.* Single-hole mounting is standard, using a ⅜ in. by 32 threads per inch as the standard mounting bushing for the larger controls.
3. *Rotation.* Rotation is by means of a standard ¼-in.-diameter shaft for the larger controls to which a knob is attached.
4. The *terminals* are solder lugs.
5. *Taps.* Taps or terminals may be brought out at intermediate points along the resistance element for any purpose, *e.g.*, for acoustic compensation at low levels. The standard positions for bringing such taps out are 35 and 65 per cent of effective electrical rotation.
6. *Multiple Controls.* Standard controls are made so that a number of circuits may be controlled simultaneously. Two or more single controls are mounted on one shaft and bushing assembly, so that rotation of the shaft will vary all the controls simultaneously.
7. *Concentric Dual Controls.* There are equipments, such as television receivers, in which a large number of circuits must be controlled independently. The use of individual single controls would require considerable space. So-called "concentric dual controls" are made to avoid this loss of space. These consist of a two-section control with one mounting bushing, using concentric shafts, the hollow shaft controlling the front section, the solid shaft controlling the rear section. Two circuits can be controlled independently, and the panel mounting space is that required for only one control.

The electrical characteristics are as follows:

1. *Voltage Coefficient.* Since the composition of the resistor element is the same as for fixed-composition resistors, the voltage characteristic is also the same.
2. *Temperature Characteristics.* The same considerations apply here as to fixed composition resistors. Figure 32 shows typical characteristics for a volume-control resistance element on phenolic sheet, for different resistance values.
3. *Noise.* Standard quantitative requirements and methods of measurement have not yet been established for this characteristic. The characteristic of importance is the noise generated as a result of the movement of the contactor across the element. This is a function of a number of factors:

a. Surface of resistor element. A smooth flat surface produces less noise than a rough irregular one.

b. Nature of solid contactor. The points or area of the slider at which contact is made to the resistance element should not change or shift as the slider is rotated, if minimum

noise is to be obtained. Such shifts produce irregular resistance changes and current distribution which produce noise. This imposes severe requirements on the flatness of both resistance element and contactor.

c. Taper or resistance-rotation curve. Smoothness and gradualness of a taper curve are important for minimum noise. Bad breaks, irregularities, and sharp changes in slope in the curve cause corresponding changes in resistance which produce noise.

d. Presence of d.c. in the resistor circuit aggravates the production of noise. This explains why diode load and sensitivity controls in cathode circuits used as rheostats are more noisy than audio-level controls.
FIG. 32. Temperature-resistance characteristics; printed resistance on phenolic sheet. Curve 1, 1,000 ohms; curve 2, 10,000 ohms; curve 3, 0.100 megohm; curve 4, 1.00 megohm; curve 5, 10.0 megohms.

4. *Power Rating.* The power rating of the film-type variable resistors is ¼ watt for the 15/16-in.-diameter size, ⅓ watt for the 1⅛-in. size, and ½ watt for the 1¼-in. size.

The solid type of variable composition resistor has a power rating of 2 watts for the 1⅛-in. size, and ½ watt for the ½-in. size. Rating based on 70°C ambient.

54. Uses for Variable Carbon Resistors. Within their power limitation these resistors may be used wherever a continuously variable resistor is required. They may be used as either potentiometers or rheostats. They find their widest use as volume controls and tone controls in radio receivers. Some of their specific uses are here listed, and some of the basic circuits illustrating these uses are shown in Fig. 33.

1. Sensitivity control for radio receivers, by varying control-grid or screen-grid potentials of r-f tubes (Fig. 33*a*).
2. Antenna control for varying r-f input to antenna tube (Fig. 33*b*).
3. Sensitivity and antenna input control, combination of Figs. 33*a* and 33*b* (Fig. 33*c*).
4. Audio-level control (Fig. 33*d*).
5. Combination load-resistor and audio-level control in diode rectifier circuit (Fig. 33*e*).
6. Tapped volume control for acoustic compensation at low levels. Resistance-capacitance circuits are shunted across one or more taps to produce varying degrees of a-f compensation at different levels (Fig. 33*f*).

7. Gain controls and faders for phonograph and a-f amplifiers.
8. Tone control in a-f amplifiers for varying a-f frequency characteristics.
9. High-frequency variable resistor when nonreactive feature is essential, as in signal generator attenuators.
10. Television controls, such as brightness, contrast, focusing.

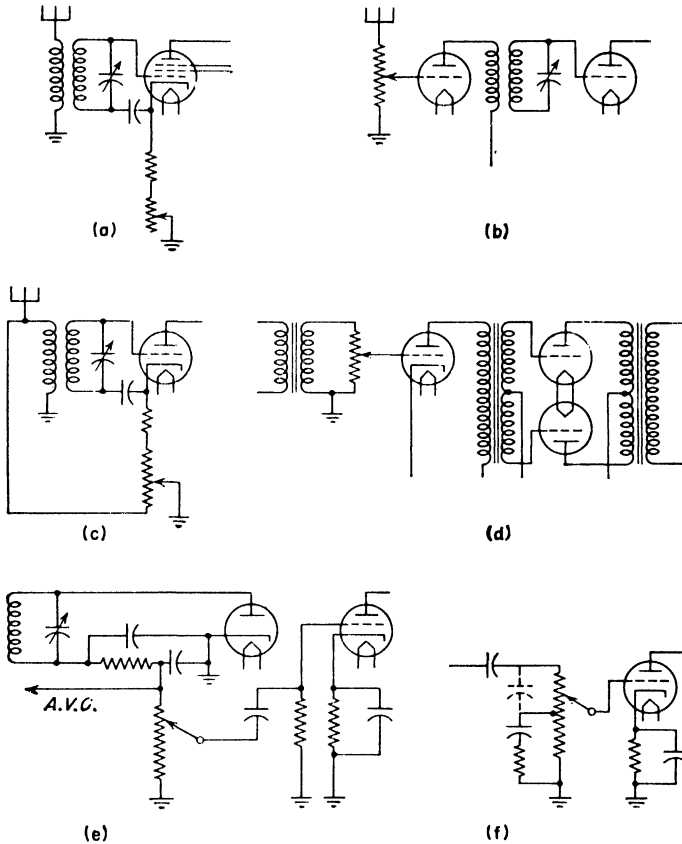
55. Tapers. The circuit considerations involved in these applications are discussed elsewhere in this handbook, particularly in Chap. 19, Receivers. However, each of these applications calls for a resistance curve, or "taper" as it is termed, which is most


FIG. 33. Typical uses of variable resistors.

suitable for it. This taper defines the law of resistance change vs. angular rotation of the variable arm. Some widely used curves are given in Fig. 34.

A suitable specification defining the taper should include:

1. Curve showing resistance variation against active angular rotation of the contactor. Where a switch is incorporated in the variable resistor, the angle taken up for operation of the switch is considered inactive. Curve should indicate whether resistance increases with clockwise or counterclockwise rotation.
2. Resistance at extreme counterclockwise end between variable arm and left terminal; this is generally called "left terminal minimum" and is specified as "less than so many ohms."

3. Resistance at extreme clockwise end between contactor and right terminal; this is generally called "right terminal minimum" and is specified as "less than so many ohms."

4. When a tap is specified, the angular location and resistance of the tap should be given. The resistance between the tap terminal and the variable arm, when located at the tap, is sometimes specified.

56. Choice of Volume-control-resistance Curve. In an audio amplifier in which the maximum output is 40 db above the minimum output, the volume control should be so made that each $\frac{1}{40}$ of the rotation should correspond to an attenuation of 1 db. If the volume control has a total attenuation of 80 db, more than is necessary on this particular amplifier, each $\frac{1}{40}$ of the rotation will correspond to 2 db attenuation since only half of the total rotation can be used. In the second case the control should be more critical than in the first case.

FIG. 34. Typical taper curves for variable resistors.

In a radio receiver the design of the volume control differs widely depending upon whether the receiver has a.v.c. or not. If not, the entire voltage gain of the receiver must be under control, perhaps 120 db. The tendency for the volume control to become noisy or to be difficult to adjust without producing violent jumps of volume change increases with the total gain that must be controlled.

The fact that a-v-c systems cannot deliver a uniform voltage to the audio detector because of the wide variations of input voltage (ranging from a microvolt to several volts) makes necessary a different shape of attenuation curve than would be used on an audio amplifier used by itself. A type of curve useful in the a-v-c receiver is shown. Here, approximately uniform attenuation of 40 db is secured in 80 per cent rotation from the maximum volume. This is the range most often used. The departure from linearity in the first 15 per cent of rotation is to keep the resistance gradient within limits representing low noise (Fig. 35).

Between 80 and 100 per cent rotation, the curve changes rapidly to provide a total attenuation of 80 db. Rapid attenuation in this region is accomplished without noise because the resistance change per decibel is small. Such a curve is much more satisfactory than a straight logarithmic line (note the 80-db curve). Units of this type are simpler to build. A tapered resistance curve such that equal increments in rotation produce equal increments in attenuation (a straight line when plotted against the logarithm of the resistance) requires that a change of 300,000 ohms take place in the first 10 per cent, 120,000 ohms in the second 10 per cent, and so on till the last 10 per cent rotation produces a change of only 75 ohms. This is true of a 500,000-ohm control with a total attenuation of 80 db.

Wear Characteristics. Variable carbon resistors necessarily have the same general electrical characteristics as fixed carbon resistors. In addition, owing to the motion of the slider on the resistance element, there is a certain amount of wear on the resistance element. This produces a change in resistance value and noise. Factors influencing these changes are as follows:

1. Hardness of resistance element which determines ability to withstand abrasion.
2. Pressure of moving contact on resistance element.
3. Smoothness of moving contact surface.

57. Variable Wire-wound Resistors. 1. *Low Power.* These are usually of the continuously variable type made by winding resistance wire on an insulating form of bakelite, fiber, or similar material, which may be arcuate in shape or a flat strip formed into an arc after winding. The form is then placed in a protective container. A metallic sliding arm is arranged to travel over the winding, thus making contact with each turn as it is rotated. The choice of wire and size is determined by the resistance and space requirements.

In general, wire-wound continuously variable resistors are wound so that the resistance changes uniformly with the motion of the sliding contact. For certain uses, it is desirable that the resistance change be nonuniform. In this case, the form on which the wire is wound is sometimes tapered so that the resistance per degree of rotation is not constant. Other methods of tapering employed are winding with variable pitch, winding sections of the control with different sizes of wire, and copperplating portions of the winding.

FIG. 35. Advantage of special taper for volume control.

The resistors are made in sizes varying from approximately $1\frac{1}{4}$ in. in diameter and $\frac{1}{2}$ in. deep to 5 in. in diameter and $2\frac{1}{2}$ in. deep. The maximum resistance varies from 10,000 ohms for the smallest size to 500,000 ohms for the largest. The standard power ratings vary from 2 watts for the smallest size to 25 watts for the largest. Usual standard ratings are 2, 3, 7, 8, 12, and 25. The power rating is based on a temperature rise of 60°C, when mounted on a steel plate $\frac{1}{16}$ in. thick and 4 to 6 in. square. This rating is based on a resistor wound linearly.

2. *High Power.* The general type of high-power variable resistors is the ceramic type. Resistance wire is wound on a toroidal ceramic core, and the winding coated with vitreous enamel and bonded to a ceramic base or otherwise mounted on materials having high temperature resistance. A sliding contactor, which may be metallic, or a graphite-metal brush is arranged to rotate around an open track on the resistor winding.

These resistors are made in sizes varying from $1\frac{1}{2}$ to 12 in. in diameter. They are made in power ratings from 10 to as high as 1,000 watts, the usual standard ratings being 25, 50, 75, 100, 150, 225, 300, 500, 750, and 1,000 watts. Standard tolerance is ±10 per cent. The maximum resistance values that can be wound are very high, based on the size of these rheostats. Since these units are intended for relatively low voltage systems in which heavy currents and high power are controlled, the maximum resistance values are generally limited to 5,000 to 10,000 ohms.

Power Rating. Power rating is the power dissipated in the total resistance of the rheostat. Linear-wound rheostats of this type having ratings of 100 watts and less are rated on the following basis: When mounted in the center of a 0.063-in.-thick steel panel, 12 in. square and vertically suspended in still air at an ambient of 40°C, the temperature rise, measured at the center of the open track, at rated power, shall not exceed 300°C. For
rheostats above this rating, under similar conditions, the temperature rise shall not exceed 350°C. Enclosed rheostats are rated at 50 per cent of this unenclosed rating.

Design Consideration. Some of the factors to be considered in design are as follows:

1. Contact between slider and resistor element should be positive.
2. Winding should not become loose on the form.
3. Sliding contact should not wear away resistance wire.
4. Resistance change per turn should be as small as possible.
5. Slider material should be such that it will not oxidize, wear excessively, or pit.

PRECISION POTENTIOMETERS

These are variable resistors designed to give a precise relationship between the displacement (linear or angular) of the slider and the resistance or voltage at the point of contact of the slider. This relationship may be linear or functional (nonlinear). These find their greatest applications in systems requiring accurate positioning such as servomechanisms, fire control, radar, computers, and automatic control devices.

58. Potentiometer Types. There are two types:

1. *Rectilinear.* The resistance element is straight and the slider displacement is linear.
2. *Rotary.* The resistance element is circular and the slider displacement is angular. The rotary type may be a single-turn potentiometer (360 deg or less rotation) or multiple-turn. Multiple-turn potentiometers are made with rotations as high as 5,400 deg or more. The discussion of any type is applicable generally to all types.

59. Potentiometer Construction. The basic elements of the precision potentiometer are the same as for any variable resistor, namely, a housing in which are assembled a resistance element and a movable arm or shaft carrying a contact which slides along the resistance element to vary the resistance. The difference resides in the precision, accuracy, and care with which every part and the assembly are made, and in the requirements which have to be met.

The resistance element is the heart of the device and is assembled in a plastic or metal case. Resistance wire is wound on an insulating form which generally is either a flat phenolic strip of rectangular cross section, or Formvar-insulated copper rod of uniform cross section. Both types may be used straight or shaped into a circle for a single-turn potentiometer. The copper rod winding may also be shaped into an accurately spaced helix to provide a multiturn potentiometer. When flat strip is used for the winding, it may be tapered or shaped to a contour to provide a nonlinear resistance change.

For a film-type resistance element the insulating base is generally phenolic for composition films, and either glass or ceramic for deposited-carbon or metal films.

The shaft or movable element carries a slider or contact which is generally a composition of noncorrosive precious metals designed to give minimum wear and noise. The shaft rotates in a sleeve or ball-bearing assembled to the case. Ball bearings are used where extremely low torque is a requirement. The case is enclosed to be dust-free. The design is such that a number of potentiometers may be assembled in tandem operated by one shaft.

Dimensions of the rotary type vary from ½ to 3 in. diameter and ½ to 3 in. long. Power ratings vary from ½ to 10 watts. The resistance varies from a few ohms to approximately 500,000 ohms, depending upon the size of the potentiometer.

60. Potentiometer Performance. The unique factors determining the electrical performance are linearity, conformance, resolution, and noise.

1. *Linearity.* This is a measure of the ability of a linear potentiometer to produce an output (voltage or resistance) directly proportional to the slider displacement (angular rotation of shaft). There are many types and definitions of linearity. Figure 36 illustrates a typical linear potentiometer in which the ideal or desired curve of resistance change with rotation is shown as a straight line. The actual curve might appear as shown. The linearity of the potentiometer is defined as the maximum per

cent deviation from the desired curve. When the curves are plotted in per cent resistance vs. per cent rotation, the per cent linearity is the difference between the two curves at the point of maximum deviation. Standard specifications for linearity usually are of the order of 0.5 to 1 per cent, but on special orders may be made as low as 0.1 per cent.

Good linearity is dependent on factors such as:
a. Uniform cross section of winding forms
b. Uniform specific resistivity of the wire
c. Uniformity of the winding pitch and its maintenance
d. Good mechanical construction such as concentricity of shaft, bearing and winding, absence of backlash

Improvement in linearity can be obtained by the use of trimming resistors at one or both ends of the potentiometer and by padding resistors at tapped points on the potentiometer.

2. *Conformance.* This term applies to functional or nonlinear potentiometers and has the same significance that linearity has to linear potentiometers. It is a measure of the degree to which the actual output curve deviates from the desired curve.

Nonlinear potentiometers are made by shaping the winding form to correspond to the desired function. In this case, lack of conformance is frequently corrected by connecting external or internal padding resistors either at both ends and/or at tapped points along the winding to distort the curve shape until the desired curve is obtained.

FIG. 36. Linearity of precision potentiometers.

3. *Resolution.* This is a measure of the precision to which the output of the potentiometer can be set. It is measured by the minimum resistance change that can be obtained by motion of the contactor expressed as a percentage of the total potentiometer resistance. The smaller the resistance change the greater the resolution. In a wire-wound potentiometer of a given resistance, therefore, the greater the number of turns the better the resolution. It is for this reason that multiturn potentiometers are so widely used, since the number of turns of wire for a given resistance increases with the number of revolutions of the shaft. However, no matter how many turns of wire are used, the minimum resistance change obtainable is the resistance of one turn.

The ideal condition, therefore, for precision setting occurs when there is a continuous stepless change in resistance. This is most nearly obtained with film-type and slide-wire resistors. In both cases the resistance change is continuous, the resistance element having the equivalent of an infinite number of turns, producing an *infinite-resolution potentiometer.* The slide-wire type, however, is severely limited in the maximum resistance value that can be obtained. This disadvantage can be partially offset by a multiturn slide-wire potentiometer. The importance of a very low resolution is evident in the case of servos where "hunting" may take place in stepwise control, the servo trying to find a resistance value or voltage which does not exist. Further, the importance of low resolution is also evident in the last important requirement of precision potentiometers, namely:

4. *Noise.* Whatever the causes, noise is the equivalent of unwanted resistance changes or spurious voltages which transmit false information. Some of the causes of noise are:

a. Resolution factor. A potentiometer with low resolution, *i.e.*, few turns or large resistance change per step, results in abrupt changes in voltage as the contact travels from turn to turn. A high resolution or large number of turns are necessary for minimum noise.
b. High contact resistance between contacts and resistance element. This may be caused by insufficient pressure of contactor to wire. Too great contact may cause too much wear. A compromise must be made.

c. The presence of dust, dirt, wear products, or other foreign matter on the resistance element. Extreme care must be exercised in manufacture to avoid this.

d. Oxidation of the resistance element of the contactor.

e. The presence of emfs in the potentiometer as a result of thermal emfs, or polarization emfs developed by dissimilar metals or impurities in the metals. This effect is extremely small.

61. Potentiometer Specifications. There are a great many variations in this class of potentiometers. Complete standardization has not yet been effected. Table 12 below is an illustration of the specifications covering a small segment.

Table 12. Typical Specifications of Precision Potentiometers

VARISTORS AND THERMISTORS

62. Varistors. Varistors is the coined name applied to a class of nonohmic conductors, whose resistance, though not manually adjustable, varies over wide ranges with voltages and/or temperature. These are made of a class of materials called "semiconductors," whose resistivities at room temperature fall between those of metallic conductors and those of insulators. The order of magnitude of these resistivities is as follows:

Resistivity in Ohm-cm

Metals	Semiconductors	Insulators
10^{-5}	10^{-2}–10^{6}	10^{6}–10^{15}

These semiconductors are usually metallic oxides, or other types of metallic compounds, which may be sintered in some inert binder such as clay. They are charac-

terized by their extreme sensitivity to voltage or temperature changes. They may be divided into three classes.

63. Low-voltage Varistors—Rectifiers. The classic examples of these are the selenium, copper-oxide, germanium, and silicon rectifiers and transistors. These are used primarily at low voltages and are characterized by their asymmetrical voltage-resistance curve; *i.e.*, the resistance is dependent on the direction of the applied voltage. They have extremely high resistance to negative voltages and low resistance to positive voltages (see Fig. 37*a*). This property is responsible for their rectifying ability. It should be noted that this is a characteristic of single-contact varistors, *i.e.*, varistors consisting of a single crystal or disk making one contact to the other electrode.

Some of the more typical applications for these voltage-varying resistors are for voltage regulation, signal clipping, balanced modulators, contact protection, and meter-overload protection.

64. High-voltage Varistors. A typical example of this class is the silicon-carbide resistor (thyrite). This, in contrast to the single-contact varistor described above, consists of a large number of silicon carbide granules sintered in a vitreous ceramic. Unlike the rectifier type, the resistance-voltage characteristic is symmetrical, *i.e.*, is independent of polarity (see Fig. 37*b*). This is explained partly by the fact that, although any single contact in the resistor mass may rectify, random distribution of large numbers of contacts in series and parallel results in equal numbers of contacts rectifying in opposite directions.

The characteristics of the high-voltage resistor depend upon the composition of material and heat-treatment. Changes in resistance of the order of 100,000 to 1 may be obtained by changes in the heat-treatment. Resistance changes of the order of 100,000 to 1 or more can be obtained by voltage changes of the order of 1,000 volts. Figure 38 shows a variety of characteristics possible with this type of resistor.

FIG. 37. Resistance-voltage characteristic of varistors: (*a*) low-voltage copper-oxide; (*b*) high-voltage silicon-carbide varistor.

The temperature coefficient is negative and a function of voltage, being higher at low voltages. At low voltages a change of 45°C may change the resistance value by a factor of 2.

65. Thermistors. This class of resistor consists of mixtures of one or more metallic oxides, such as ferric oxide, Fe_2O_3, nickel oxide, NiO, manganese dioxide, MnO_2, sintered in inert binders, such as clay. These resistors are temperature-sensitive and are characterized by an extremely high negative T.C. The explanation in simplified form is that at low temperatures semiconductors have relatively few "free" or conduction electrons, most of them being bound to their respective atoms; hence the resistivity is high. As the temperature is increased more and more of the electrons in bound states acquire energies sufficient to carry them over into "free" energy states, where they can be accelerated by an electric field; hence the resistance decreases, which accounts for the high negative T.C.

There are several methods of controlling the resistance, the more prominent of which are as follows:

1. *External heating*, or controlling the ambient temperature
2. *Direct heating*, in which the circuit current passes directly through the thermistor, thus heating the thermistor and altering its resistance

3. *Indirect heating*, in which the thermistor is placed inside or near a heating coil that carries the control current, and the heat thus generated controls the thermistor resistance

66. Static Self-heat Thermistor Characteristics (Voltage-Current). The current-voltage relationship in thermistors is unique. Ohm's law is not always obeyed since thermistor resistance will vary when the current reaches a point where self-heating begins. Figure 39 illustrates this. For small currents, the power developed is too small to cause appreciable self-heating and the resistance remains constant. The voltage-current relationship thus follows Ohm's law. As the current is increased, however, the power developed becomes sufficient to heat the thermistor and resistance
FIG. 38. Characteristics obtainable in silicon-carbide varistors.

decreases. The voltage is less than it would have been had the resistance remained constant. At some current the voltage will reach a maximum value and will then remain constant or decrease as current is increased. This relationship is considered in a static condition, allowing the voltage to reach an equilibrium value after each current increase.

A typical static characteristic is shown in Fig. 39. At some value of current the voltage reaches a peak value, known as the self-heat voltage; beyond this point the curve has a negative slope. Although the specific curve shapes vary for each type of material, they all show the same general form. An interesting feature of this curve is the falling voltage characteristic with increasing current to the right of the maximum voltage point. This shows a negative resistance characteristic, similar to that displayed by an arc, such as the Poulsen arc, indicating possible uses as an oscillator.

67. Dynamic Self-heat Thermistor Characteristics (Current-Time). The resistance variations resulting from self-heating are not instantaneous. Because of thermal inertia a certain interval of time elapses before the equilibrium current of a thermistor circuit is attained. When a voltage is applied across a thermistor there is a delay in reaching the equipment current. The initial current is determined by the unheated resistance of the element. As the thermistor heats up because of I^2R power, its resistance decreases and current increases. A build-up of current takes place until it is limited by the circuit resistance. Where necessary, a load resistance is placed in

series with the thermistor to limit the current to such a value that the I^2R power will not heat the element above its maximum recommended temperature. No load resistance is used where the applied voltage does not heat the thermistor above the recommended temperature.

A typical dynamic characteristic is shown in Fig. 40.
FIG. 39. Voltage-current characteristic of iron-oxide thermistor.
FIG. 40. Time characteristic of directly heated thermistor.

68. Applications of Negative-temperature Coefficient Resistors. By virtue of their high negative-temperature coefficients of resistance, their time constants, and their peculiar volt-ampere characteristics, thermistors are useful in a number of ways, a few of which are mentioned here:

1. *Resistance Thermometers.* A thermistor in series with an ammeter and constant-voltage source will indicate temperature when the ammeter is properly calibrated. Simple refinements of this system make it possible readily to indicate changes in temperature as small as 0.0005°C.

2. *Temperature Controllers.* Related to their use as thermometers, thermistors can be employed as temperature controllers.

3. *Time-delay Devices.* Owing to the thermal inertia of thermistors, the current through them will increase for a while after voltage is applied, as the thermistor heats up and the resistance decreases. This fact can be made use of to provide time delays ranging from a few milliseconds to several minutes.

4. *Motor Starters and Overcurrent Protection.* The high initial cold resistance of a thermistor, which decreases rapidly as it is heated by current flowing through it, is useful in motor protection or in other devices that draw high initial starting or heating-up currents.

5. *Temperature Compensation.* By proper choice and connection of thermistors the positive temperature coefficient of resistance of many passive networks can be neutralized to give a resultant network whose resistance is substantially independent of temperature over wide limits.

6. *Wattmeters.* Thermistors have been used to measure power, especially in the u-h-f band, by measuring their change in d-c resistance as they absorb all, or a given fraction, of the power to be measured.

7. *Manometers.* Since the dissipation constant of a thermistor depends on the thermal conductivity of the surrounding medium and this in turn depends, in the case of gases, on the pressure, thermistors can be readily used as sensitive pressure gages for gases. Through a similar mechanism they can also be used as velocity meters for gases or liquids.

8. *Automatic Gain Control.* By incorporating a thermistor in the feedback circuit of a negative feedback amplifier, the amount of feedback voltage can readily be varied automatically to compensate for changes in the output signal. Many types of such AGC circuits have been devised.

9. *Amplifiers, Oscillators, and Modulators.* Since thermistors can be made to display negative resistance characteristics, they can, theoretically at least, be used as oscillators, amplifiers, and modulators. Such devices actually have been made in laboratories and have functioned well at low and audio frequencies, but there are still many difficulties that prohibit their practical use at this time.

RESISTOR STANDARDS AND SPECIFICATIONS

There is considerable activity in the radio industry toward establishing standards and specifications for the performance of all components including resistors. Prior to the Second World War, RETMA had a program of standards under way which were aimed at satisfying commercial requirements. The advent of the war introduced conditions of operation encountered by the military so far outside the commercial orbit that new military specifications for components were set up. For example, ambient temperatures between −50 and 100°C and even higher had to be considered. Operation at altitudes in excess of 30,000 ft with the resultant low barometric pressure placed more severe requirements on components. As a result, two sets of standards, commercial and military, exist for components. However, developments in the components field are in the direction to make these two sets of standards converge.

69. Resistor Tests. Performance specifications and tests have become so extensive that it is not possible to give them in detail. The following is a list of standard tests, commercial and military, to which resistors are subjected. The detailed procedures can be obtained from the specific standard specifications listed.

Standard Tests Applied to Resistors

Test	Applied to
Resistance measurement	All types of resistors
Power rating by measurement of temperature rise	Fixed power resistors
Voltage coefficient	Fixed composition resistors
Temperature-resistance characteristics between −55 and 105°C	All resistors except variable composition
Rapid temperature cycling between −55 and +85°C	All resistors except fixed power wire-wound resistors
Dielectric strength or voltage breakdown	All resistors
Vibration	All resistors
Noise (rotational)	Variable composition resistors and precision potentiometers
Life test at rated load at specified ambient	All resistors except fixed power wire-wound
Short-time overload	All resistors
Humidity: 90 to 95% RH at 40°C, or humidity-load cycle at 25 to 65°C	All resistors
Salt-water cycling	External-meter resistors, precision wire-wound resistors and low-power wire-wound resistors
Thermal shock	Fixed power resistors
Wear test	All variable resistors
Low-temperature exposure	Fixed film (high-stability) composition resistors, fixed and variable
Terminal strength	All wire and lug types except on variable resistors

70. Resistor Specifications. The industry or commercial specifications are prepared by the engineering division of The Electronic Industries Association (EIA) and can be obtained from the EIA Engineering Office.[1] The military specifications

[1] 11 West 42d St., New York 36, N.Y.

for resistors are the Joint-Army-Navy-Airforce Specifications (abbreviated MIL) prepared by (and also obtainable from) the Armed Services Electro-Standards Agency (ASESA).[1] The list below gives the specifications now in existence.

Resistor type	Military specification	Commercial RETMA
Fixed, composition (insulated)	MIL-R-11B	RS-172
Fixed, wire-wound (accurate)	MIL-R-93A	
Fixed, film (high-stability)	MIL-R-10509B	
Fixed (composition film, very high frequency)	MIL-R-10683A	
Fixed, wire-wound (low-power)	JAN-R-184	REC-117
Fixed, non-wire-wound (power type)	MIL-R-11804B	
Fixed, wire-wound (power type)	MIL-R-26C	RS-155
External meter (high voltage, ferrule terminal)	JAN-R-29	
Variable, composition	JAN-R-94A	REC-121B
Variable, wire-wound (low operating temperature)	JAN-R-19	
Variable, wire-wound, precision	Proposed MIL-R-12934A	
Variable (wire-wound, power type)	MIL-R-22A	TR-133

CHAPTER 3

INDUCTANCE;[1] MAGNETIC MATERIALS[2]

By F. G. Webber and Raymond L. Sanford

Part 1: INDUCTANCE

1. Definitions and Units. Inductance is that property of an electrical circuit whereby changes in the current flowing through it produce changes in the magnetic field associated with the current such that a counter emf is set up in that same circuit or in neighboring ones. If the emf is set up in the same circuit, the phenomenon is called "self-inductance"; if in a neighboring circuit, it is called "mutual inductance." Inductance is an effect exactly as inertia is an effect in a mechanical system. Inertia is that fundamental property of matter which causes a body to resist a change in its state of rest or motion. The important points are (1) that a change is necessary and (2) that the effect is to resist the change.

Inductance is measured by the emf produced in a conductor by unit rate of variation of the current. The practical unit of inductance is the *henry* (h). The henry is that inductance in which an induced emf of 1 volt is produced when the inducing current is changed at the rate of 1 amp per sec.

Since the henry is a rather large unit, especially in radio engineering work, it is commonly subdivided into two smaller units: a one-thousandth part, the millihenry (mh) = 10^{-3} henry; and a one-millionth part, the microhenry (μh), = 10^{-6} henry.

2. The Inductor. A straight conductor carrying a current has the property of inductance and, as will later be shown, is sometimes used as an inductor. However, in other configurations this property can be enhanced to become more useful. The most common inductors are coiled conductors. Since inductance is a magnetic effect, coiling the conductors gives a more concentrated field pattern. Flux set up by one turn of the coil links mutually with other turns of the coil, thereby increasing the total inductive effect. It follows that the closer the turns, the greater is the inductance. The design of an inductor would seem to be a relatively simple matter. However, it is not possible to construct an inductor capable of pure and simple inductance. (1) There is no perfect conductor and, therefore, losses in the form of resistance are introduced. (2) Distributed capacitance exists between turns of a coil and between the conductor and surrounding objects. The actual inductor is always a combination of resistance, inductance, and capacitance. The true inductance is the absolute or theoretical inductance. The apparent inductance is the effective inductance at any frequency, *i.e.*, the inductive minus the capacitive effect.

3. Resistance Effects. The reason for the difference between the d-c and the r-f resistance of a conductor is the so-called "skin effect." Consider two small filaments of a conductor, one filament at the center and one near the surface of the conductor. All the flux produced by the current through the conductor will link the center filament, but the flux within the conductor will not link the filament near the surface. This means that the center filament will have a higher self-inductance than the surface filament. This higher self-inductance means a higher reactance path for the current in the conductor. More current, therefore, flows at the conductor surface. The redistribution of the current forces more current through less of the conductor, giving higher losses and more heating. The r-f resistance can become several times the d-c resistance. See Sec. 8, Chap. 2, for ratios of a-c to d-c resistance.

[1] By F. G. Webber, F. W. Sickles Div., General Instrument Corp.
[2] By Raymond L. Sanford, National Bureau of Standards.

Since the smaller the conductor, the less the skin effect, if the conductor is broken down into many small strands, twisted about ten turns per foot and each strand insulated from the others, the skin effect is lessened. Such wire is known as "litz" wire. Skin effect is a function of the following factors:

$$d\sqrt{\frac{\mu f}{\rho}}$$

where d = diameter of conductor
μ = permeability of conductor
ρ = specific resistance of conductor
f = frequency

For air-core inductors, skin effect is the major consideration; for iron-cored or copper-cored inductors eddy-current and hysteresis losses in the core reflect as resistances in the coil. Both these losses vary with frequency.

The eddy-current loss for any material may be expressed by

$$W_e = eVt^2f^2B_{max}^2$$

where e = loss per unit volume
V = volume
t = thickness of laminations or particle size
B_{max} = maximum flux density
f = frequency

The hysteresis loss for iron, according to the Steinmetz empirical law, is

$$W_h = nfVB_{max}^{1.6}$$

where n = loss per unit volume
V = volume
B_{max} = maximum flux density
f = frequency

The total loss expressed in watts in an iron-cored inductor is

$$W = I^2R_{ac} + W_h + W_e$$

Another factor affecting the resistance of an inductor comes into play when that inductor "couples" with other circuit elements. If current is induced in the coupled circuit, losses occur and the resistance is increased. The general definition of effective, equivalent, or apparent resistance is such that this resistance multiplied by the square of the effective value of the current gives the true average rate at which heat energy is dissipated.

4. Distributed Capacitance Effects. The distributed capacitance can be assumed to be a capacitance shunted across the inductance. The effect is to give an apparent inductance that is less than the true inductance. The higher the distributed capacitance, the greater is the ratio of true to apparent inductance. Furthermore, because this distributed capacitance has dielectrics other than air in many cases, other losses can be introduced as dielectric losses. See the chapter on Capacitance for a further explanation of such losses.

The distributed capacitance of a multilayer coil, *e.g.*, a universal winding, is a highly complex thing. Capacitances occur between layers as well as between turns. The result is a network of capacitors in series, in parallel, and in series-parallel, which may cause the total distributed capacitance to increase or decrease as the inductance increases. This effect is shown in Table 2, which gives the approximate distributed capacitance of choke coils. This also explains one reason why the Q of a coil may increase with inductance up to a point and then begin to decrease.

The distributed capacitance of a single-layer solenoid is a simpler function and is approximately proportional to the radius of the form and independent of the number of turns and the winding length for solenoids of the same inductance.

5. Figure of Merit, or Q. To judge the quality of an inductor, which of necessity cannot be perfect, a figure of merit is used. This figure of merit, or Q, gives an idea of the ability of an inductor to perform its primary function, that of supplying inductance at some given frequency. Q is defined as the ratio of inductive reactance to effective resistance. Therefore, the higher the true inductance, the lower the distributed capacitance, and the lower the losses from all sources, the higher the Q. Q varies with frequency since both the reactance and the losses vary with frequency.

FIG. 1. Effect of Q on sharpness of resonance.

Power factor is the ratio of impedance to resistance for any circuit. Since, for all practical inductors, the impedance and the reactance are nearly the same, the power factor is very nearly the reciprocal of Q.

$$Q = \frac{X}{R} = \tan \phi$$

$$\text{Power factor} = \frac{R}{Z} = \cos \phi$$

where ϕ is the angle between Z and R in a right-angled triangle with a hypotenuse of Z. For very large angles, the cosine is approximately equal to the reciprocal of the tangent, the cotangent. If the Q of the inductor is 10 or more, its power factor will be within ½ per cent of the reciprocal of the Q.

FIG. 2. Q vs. frequency for various types of windings: curve 1, two-layer bank winding; curve 2, progressive universal winding; curve 3, solenoid winding; curve 4, universal winding. All coils are 250 μh, wound with $^{7}/_{41}$ SSE wire on $^{7}/_{8}$-in.-OD phenolic forms.

Q has another significance, that of showing the relative sharpness of resonance of series-resonant circuits. If the absolute value of the admittance of the circuit is plotted against frequency, a peaked resonance curve is obtained. If the resistance is increased, the admittance will be decreased at all frequencies but much more markedly near the resonant frequency. The curve will be much flatter under these conditions. The less the resistance, the steeper and sharper the curve will be, resulting in a more selective circuit. Since the inductor has the greatest part of the resistance of the circuit, the Q of the inductor is a good indicator of the expected selectivity of the circuit. High Q means good selectivity.

The curves in Fig. 1 show the sharpness of resonance for both good and poor Q windings. The curves in Fig. 2 show the Q vs. frequency characteristics for several types of windings.

MEASUREMENTS OF INDUCTANCE

The story of the various methods of measurements to be discussed here is more thoroughly covered in the chapters on electrical measurements. However, the practical problems involved in measurements concerned with inductors will be considered.

6. Apparent and True Inductance. Apparent inductance may be measured by finding the capacitance necessary to resonate the inductor to a given frequency. Such

measurements are frequently made since standard calibrated capacitors and frequency sources are usually handy in the laboratory. The apparent inductance is then calculated from the formula

$$L = \frac{1}{4\pi^2 f^2 C}$$

where L is in henrys, f in cycles, C in farads, or

$$L = \frac{2.533 \times 10^4}{f^2 C}$$

where L is in microhenrys, f in megacycles, C in micromicrofarads.

Apparent inductance matching is used in the production testing of inductors when the beat-frequency or single-frequency method of testing is employed. In this case the inductor under test is compared with a standard or set-tested inductor by comparing the amount of capacitance required to tune each inductor to the same frequency.

True inductance measurements are approximated on the 1,000-cycle impedance bridge since, for most inductors used at radio frequencies, the reactance of the distributed capacitance is very high at 1,000 cycles and in parallel with the comparatively low inductive reactance it has little effect. The effective resistance is taken care of in the bridge balance.

True inductance may also be measured by finding the amounts of capacitance required to resonate the inductor to two different frequencies and then calculating the inductance by the following formula:

$$L = \frac{n^2 - 1}{4\pi^2 f_1^2 (C_2 - C_1)}$$

$$n = f_1/f_2$$

where f_1 and f_2 = the two frequencies

C_1 and C_2 = capacitances required to resonate at f_1 and f_2

The effect of distributed capacitance is eliminated as is shown by the derivation of the general true inductance formula:

$$f_1 = \frac{1}{2\pi \sqrt{L(C_1 + C_d)}} \tag{1}$$

$$f_2 = \frac{1}{2\pi \sqrt{L(C_2 + C_d)}} \tag{2}$$

$$n = \frac{f_1}{f_2} \quad \text{or} \quad f_1 = nf_2 \tag{3}$$

Substituting Eq. (3) in Eq. (1),

$$n^2 f_2^2 4\pi^2 = \frac{1}{L(C_1 + C_d)} \tag{4}$$

Substituting Eq. (2) in Eq. (4),

$$\frac{n^2}{L(C_2 + C_d)} = \frac{1}{L(C_1 + C_d)}$$

whence

$$C_d = \frac{C_2 - n^2 C_1}{n^2 - 1} \tag{5}$$

Substituting Eq. (5) in Eq. (1),

$$f_1^2 4\pi^2 = \frac{1}{L\left(C_1 + \frac{C_2 - n^2 C_1}{n^2 - 1}\right)}$$

whence

$$L = \frac{n^2 - 1}{4\pi^2 f_1^2 (C_2 - C_1)}$$

which is the general true inductance formula.

Example: If $f_2 = 600$ kc, $f_1 = 1{,}200$ kc, $C_2 = 130$ μμf, $C_1 = 30$ μμf, then

$$n = \frac{1{,}200}{600} = 2$$

$$\begin{aligned} L &= \frac{2^2 - 1}{4\pi^2(1.2 \times 10^6)^2(130 - 30)10^{-12}} \\ &= 5.28 \times 10^{-4} \text{ h} \\ &= 528 \ \mu\text{h} \end{aligned}$$

and

$$\begin{aligned} C_d &= \frac{C_2 - 4C_1}{3} \\ &= \frac{130 - (4 \times 30)}{3} = 3.33 \ \mu\mu\text{f} \end{aligned}$$

For simplicity of calculation and equipment design, it is common to choose the frequencies as the fundamental and the second harmonic so that

$$\frac{f_1}{f_2} = 2 \qquad L = \frac{3}{4\pi^2 f_1^2 (C_2 - C_1)} \qquad \text{or} \qquad \frac{0.07599}{f_1^2(C_2 - C_1)}$$

Note also that this gives a method for the measurement of distributed capacitance from the general formula (5) $C_d = \frac{C_2 - n^2 C_1}{n^2 - 1}$ or, for the more usual case where $n = 2$, $C_d = \frac{C_2 - 4C_1}{3}$.

True inductance measurements by this method are sometimes used but are generally spurned in favor of the simpler 1,000-cycle bridge measurements.

True inductance or two-frequency inductor matching is often used in the production testing of inductors to ensure more accurate "tracking" of the r-f part of single-dial radio sets.

7. Two-frequency Test. The test equipment (Fig. 3) consists of two oscillators, one used as a reference and the other used with the inductor under test. The signals
FIG. 3. Two-frequency or true-inductance matching setup.

from the two oscillators are mixed, fed into an amplifier and thence to either an audible or a visual beat indicator to show when the two oscillators are at the same frequency. The reference oscillator is set to the lower of the two frequencies (in the example, 600 kc). A standard inductor, either tested in a radio set or accurately measured as to its true inductance, is placed in a test jig so that it forms the inductance for the

second oscillator circuit. A variable capacitor is shunted across the inductor. This capacitor is sufficient to tune the inductor to the second harmonic of the reference oscillator (in the example, 1,200 kc). A switch is provided that allows approximately three times that capacitance to be added in parallel when desired. With the additional capacitance, the inductor will tune to the fundamental frequency (600 kc). The standard inductor is tuned to the second harmonic and then, without disturbing this capacitor, the second capacitor is added and with it the inductor is tuned to the fundamental frequency. Both capacitor readings are noted. An unknown inductor may now be matched to the standard by removing the standard from the test jig and inserting the other inductor. That inductor is then adjusted until both capacitor readings are within the desired tolerance of the standard. The difference in capacitance readings between the unknown and the standard at the second harmonic gives an indication of the differences in their distributed capacitances, and the difference in readings at the fundamental frequency gives the difference in true inductance between the two.

8. Measurement of Distributed Capacitance. One very common method of measuring distributed capacitance has already been discussed under measurement of inductance. That method must be used with caution since it depends upon the difference of two numbers of much greater magnitude than the resulting distributed capacitance and is, therefore, liable to introduce large errors.

It is possible to determine the natural resonant frequency of an inductor by placing it in parallel with another resonant circuit whose resonant frequency is calibrated and can be varied. The frequency of the calibrated circuit is varied until the introduction of the inductor being measured does not affect the tuning but only the circuit Q. This is the natural resonant frequency of the inductor since at that point it has no reactance but acts as a pure resistance loss. Assuming that the inductance remains relatively constant over a range of frequencies, the distributed capacitance can then be found by measuring the capacitance required to tune the inductor to some lower frequency, far removed from the natural resonant frequency, and then calculating the distributed capacitance by the formula

$$C_d = \frac{f^2 C}{f_n^2}$$

where f = lower frequency
C = capacitance to tune to that frequency
f_n = natural resonant frequency

In practice f_n is about ten times f. This method is more accurate than the previous method, especially for distributed capacitances of less than 10 $\mu\mu$f.

9. Measurement of Q. The figure of merit, Q, is most readily measured on Q meters that have been calibrated to read directly over large frequency ranges. The Q meter is based on the fact that the ratio of the voltage developed across the capacitor in a resonant circuit to the voltage introduced into the circuit is equal to Q. Thus a measured current from an oscillator flows through a resistor of very low resistance in series with the inductor to be measured, introducing known voltage into the circuit. A built-in calibrated capacitor completes the series circuit. A voltmeter, calibrated directly in Q, measures the voltage developed across the capacitor. This voltmeter has negligible power consumption.

In resonant circuits containing a well-designed, low-loss capacitor, the resistance of the capacitor is negligible as compared with the resistance of the inductor. The total losses can be considered as occurring in the inductor alone. Under these conditions,

$$Q = \frac{f_r}{f_2 - f_1}$$

where f_r is the resonant frequency, f_1 and f_2 are the frequencies above and below resonance at which the power dissipated is one-half the power dissipated at resonance, and

the current is 0.707 times the current at resonance. Also

$$Q = \frac{C_r}{C_2 - C_1}$$

where C_r is the capacitance at resonance, and C_1 and C_2 are the capacitances corresponding to frequencies f_1 and f_2. With these formulas, Q measurements may be made with equipment usually available around a laboratory.

10. Measurement of Mutual Inductance. The simplest method of measuring mutual inductance is the Felici balance in which the unknown mutual inductance is compared with a variometer whose mutual inductance with respect to rotation has been calibrated. The primaries of both inductors are connected in series across an a-c source, usually 1,000 cycles. The secondaries are also connected in series, so that the voltages induced in them oppose each other, and in series with a null detector, usually a pair of headphones with a suitable amplifier. At the null, the mutual inductance of the unknown is equal to the mutual inductance of the known calibrated variometer.

If an inductance bridge is available, the mutual inductance, M, may be found by measuring the total inductance of the primary and secondary inductances in series aiding and then in series bucking. M is calculated from the formula

$$L_M = \frac{L_{\text{aiding}} - L_{\text{bucking}}}{4}$$

Coefficient of coupling is a term sometimes encountered in working with coupled inductors. This coefficient, K, is the ratio of the mutual inductance to the geometric mean of the primary and secondary inductances, or

$$K = \frac{L_M}{\sqrt{L_p L_s}}$$

TYPES OF INDUCTORS

11. Straight Conductors. Since any conductor carrying a current has the property of self-inductance, the simplest form of inductor is a straight wire. Straight wires are used as inductors in h-f applications where the inductance must be very low. In some cases the inductance is furnished by the current flowing along the plates of the variable tuning capacitor. At the frequencies at which straight conductors become important as inductors, many other complications arise not within the scope of a discussion of inductors; therefore, they are simply mentioned here without any detail.

For reference, a straight piece of No. 10 AWG wire 1 in. long has an inductance of about 0.015 μh at low frequencies, if the return conductor is assumed to be remote.

FIG. 4. Solenoid with spaced section for adjusting the inductance.

12. Single-layer Solenoid Windings. The single-layer solenoid winding is probably the most important type of inductor for frequencies from about 1 to 100 Mc, or higher. It has the advantage of being fairly simple. Its inductance can be varied by spacing a fraction of the total turns away from the main body of the winding (Fig. 4). Then by moving a few of the spaced turns nearer to the main body, the inductance can be raised slightly. By moving a few turns away from the main body to the spaced portion, the inductance can be lowered slightly. Such adjustment of inductance is important in the tracking of the r-f portions of superheterodyne receivers.

The single-layer solenoid winding has the further advantage of low distributed capacitance, since the first and last turns which have the greatest voltage developed between them are relatively far apart. The voltage between any two turns is only $1/n$ of the total voltage if n is the total number of turns.

This type of winding can be made to have a fairly constant inductance with temperature changes since it can be wound in grooves in the coil form or firmly cemented to the form.

For a given design, Q variations of ± 5 per cent and inductance variations of ± 2 per cent can be expected in the normal production of solenoids. In the case of coils used in broadcast receivers whether the windings are solenoids, universals, progressive universals, or banks, the common commercial inductance tolerances after adjustment are $\pm \frac{1}{2}$ per cent for oscillator coils and ± 1 per cent for r-f and antenna coils. See Table 1 for a list of common h-f solenoids.

Table 1. High-frequency Solenoids

OD, in.	Wall, in.	Wire	Tpi*	Turns	Inductance, μh	Q	Frequency, Mc
1	3/64	20E	20	5 9/16	1.1	105	7

1/2	1/16	22E	36	24 1/2	4.3	112	7

* Tpi is turns per inch for grooving.
NOTE: All forms are phenolic, grooved.

13. Multilayer Solenoids. Multilayer solenoids are usually wound with the first layer running from left to right, the next running from right to left, etc. (Fig. 5). If the layers are separated by paper, the winding is known as a "paper-layer" solenoid. This type of winding has the disadvantage of high distributed capacitance since the beginning of one layer and the end of the next layer, which are at high potential difference, are directly above one another. Adding paper between the layers serves to reduce the distributed capacitance, improve the voltage breakdown between layers, and provide a smooth winding surface for the next layer. Multilayer solenoids are used at power and audio frequencies but never at radio frequencies where distributed capacitance is important.

FIG. 5. Cross section of multilayer solenoid winding.

14. Universal Windings. The universal winding is a comparatively narrow multilayer winding in which the conductor spirals back and forth across the width of the winding as the winding is built up. This results in a self-supporting lattice type of construction. By changing the ratio of the pitch of this spiral to the number of turns, varying numbers of crossovers per turn and turns per layer can be obtained. The distributed capacitance is fairly low since turns with high potential difference simply cross each other and do not lie parallel to one another for appreciable distances. Large inductances can be efficiently put into small spaces through the use of universal windings. They are commonly found in r-f chokes, i-f transformers, high-impedance primaries, etc.

By making the universal winding in several sections of pi's side by side on the form,
FIG. 6. Single- and three-pi windings.

the distributed capacitance can be further reduced and, since the field pattern is elongated, the effect of placing a shield around the winding is diminished. The effective diameter is also decreased, a fact that can be important when powdered-iron cores are used. Honeycomb coils were a type of universal winding with relatively few, widely spaced turns per layer giving a typical "honeycomb" appearance. The universal winding can be varied in inductance somewhat for tracking purposes. It can be reduced by squeezing, which shortens the effective diameter. The inductance may

Table 2. Typical Universal Wound Choke Coils

All coils are two-cross, single-pi universals. Coils of 0.5 to 20 mh are ¼ in. wide wound with No. 36 SSE wire. Coils of 25 to 70 mh are wound with No. 38 SSE wire and are 5/16 in. wide. All values are approximate.

be raised by squeezing the thickness of the winding to increase its effective diameter. Such distortion of the winding is not too desirable since it makes for poor stability, reduces Q, and increases distributed capacitance. Pi windings may be moved closer together or farther apart to accomplish the same end with the same disadvantages.

Table 4. Effect of Width of Winding on Q*

* 1-mh coil, 7/41 SSE wire, 2 crosses per turn, single pi.

Universal windings are commonly used for inductors from 10 μh to 1 h. They may have Q's up to about 150. Common Q variations found in commercial windings of the same design and inductance are ±10 per cent. The usual inductance tolerance for unadjusted windings is ±5 per cent. See Tables 2 to 7 for data on universal windings.

An article by A. W. Simon[1] covers the general theory of universal windings and gives other references to work done on the mathematical study of these windings.

15. Bank Windings. Banked or bank windings are another form of multilayer windings in which a special arrangement of the turns in the various layers tends to reduce distributed capacitance. The

arrangement is shown in Fig. 7. This type of winding is difficult to produce and has, therefore, lost favor.

Commercial Q variation for a given design is ± 10 per cent while the inductance variation is about ± 5 per cent for unadjusted windings. See Table 9 for a comparison of bank and progressive universal windings.

16. Progressive Universal Windings. To a large degree, progressive universal windings have supplanted the bank windings. This winding is produced in a manner similar to the universal winding except that instead of spiraling back and forth in the same area, the spiraling also progresses along the form and gives a winding that is spread out horizontally rather than built up vertically. A simple progressive winding looks somewhat like a bank winding. Because it is possible to vary the crossovers per
FIG. 7. Cross section of bank windings.
FIG. 8. Appearance of progressive universal winding.

turn as well as the rate of progression, a great variety of windings is possible. This type of winding helps make possible the high-Q permeability-tuned inductors to be discussed later.

The commercial variations in Q and inductance of a given design of a progressive universal winding are the same as those for universal and bank windings, ± 10 and ± 5 per cent, respectively.

An article by A. W. Simon[1] gives some of the theory of this complex winding type.

17. Other Types of Windings. There are a few other types of windings of more or less importance. For example, the flat spiral is widely used in loop antennas for broadcast receivers. Spider-web, basket-weave, and similar windings are cumbersome and difficult to produce. The toroidal winding has its conductor wound on the surface

[1] *Proc. IRE*, December, 1945.

of a toroid. When carefully made, the field is almost completely self-contained. It requires little shielding and is sometimes used in making inductance standards. When a high-permeability core is used, a maximum inductance can be obtained in a minimum space. Such toroids are finding increased use in the missile and computer fields.

18. Iron-cored Inductors. Since the permeability of the medium has a definite effect on the flux that causes self-inductance, it is obvious that the inductance of an air-cored winding can be increased by introducing material, such as iron, into the

Table 10. Toroidal Iron-core Coils

This table* gives data derived from measurements on toroidal cores of the most important iron powders available on the market. All toroids were prepared in the same way for reasons of comparison, *i.e.*, with 4 per cent bakelite (type 7095), 2 per cent Sterotex for lubrication, 50 tons per sq in. pressure, and 50 g weight. Their OD is 2.25 in., ID 1.50 in., and they are wound with a single layer of 200 turns of No. 25 magnet wire.

The data were obtained for the most part according to the method of V. E. Legg. *Bell System Tech. J.*, **15,** 39, 1936. Thus, the following units apply:

Density, g/cm³
Permeability, gausses gilbert/cm
Hysteresis loss coefficient, 10^{-3} ohm/h/gauss cycle
Eddy-current loss coefficient, 10^{-6} ohm/h/cycle squared
Magnetic stability, percentage change of permeability after 4 amp passage through winding

Material	Density	Permeability	Hysteresis	Eddy current coeff	Stability
Carbonyl L	5.7	24.8	3.1	0.13	+1.4
Carbonyl C	5.7	16.7	1.1	0.14	+0.6
Carbonyl E	4.9	10.4	0.3	0.11	+0.6
Carbonyl TH	4.9	9.6	0.3	0.10	+0.18
Carbonyl SF	4.8	8.1	0.3	0.10	+0.15
Electrolytic	5.6	23.4	2.4	0.33	−0.17
Hydrogen reduced, 1	5.6	18.4	2.6	0.12	+1.3
Hydrogen reduced, 2	5.5	16.9	1.0	0.12	+1.6

Magnetite, 2	4.0	5.7	6.8	0.21	−1.6
Magnetite, 3	3.5	3.1	0.3	0.085	+0.10

* All data from General Aniline and Film Corporation.

winding to increase the permeability of the medium. However, the introduction of the material also introduces a new source of losses. Magnetic losses due to hysteresis and eddy currents were discussed in a preceding section. At low frequencies, in the power or audio region, laminating the iron will substantially reduce the eddy-current losses. As long as large amounts of d.c. are not present in the inductor, which would tend to produce saturation of the iron and hence a nonlinear inductance as the current is varied, the only major problem is to get as much permeability as possible in order to get as much inductance as possible in a small space.

At radio frequencies it is not possible or practical to make laminations thin enough to reduce the losses to a sufficient degree. An entirely different technique is, therefore, employed in making the core: powder metallurgy. In this process the iron is in a very finely powdered state, produced either mechanically or chemically. The powder is combined with suitable binders, compressed, and sintered to produce a very compact mass which nonetheless consists of separate particles with an average size of 10 microns or less.

Carbonyl iron powders are obtained by thermal decomposition of iron pentacarbonyl. There are five different grades in production, designated as L, C, E, TH, and SF powder. Each of these is obtained by special process methods and has its special field of application. The particles making up the powders E, TH, and SF are spherical with a characteristic structure of increasingly larger shells. The particles of L and C are made up of homogeneous spheres and agglomerates.

The chemical analysis, the weight-average particle size as determined in a Roller air analyzer, the "tap density," *i.e.*, the density of the loose powder packed by tapping the container in a prescribed manner, and the apparent density or bulking factor as determined in a Scott volumeter are given in Table 11 for the five grades.

Table 11*

Grade	Chemical analysis, per cent			Wt—ave. diam, microns	Tap density, g/cm³	Apparent density, g/cm³
	Carbon	Oxygen	Nitrogen			
L	0.005-0.03	0.1 -0.2	0.005-0.05	20	3.5-4.0	1.8-3.0
C	0.03 -0.12	0.1 -0.3	0.01 -0.1	10	4.4-4.7	2.5-3.0

SF	2.17	62	71	78	84	100

* All data from General Aniline and Film Corporation.

NOTE: Q values actually measured can be obtained by multiplying the rows, respectively, by 0.78, 1.09, 1.25, 2.63, and 1.62.

L and C powders are also used as powder-metallurgical material because of their low sintering temperatures, high tensile strengths, and other very desirable qualities. Sintering begins below 500°C, and tensile strengths reach 150,000 psi.

With reference to the chemical analysis shown in Table 11, it should be noted that spectroscopic analysis shows the rest to be iron with other elements present in traces only.

Carbonyl iron powders are primarily useful as electromagnetic material over the entire communication frequency spectrum.

Table 12 gives relative Q values and effective permeabilities for the different grades of carbonyl iron powder. The values are derived from measurements on straight cylindrical cores placed in simple solenoidal coils. Although the data were not obtained at optimum conditions, the Q values as expressed in percentage of the best core give an indication of the useful frequency ranges for the different powder grades.

FIG. 9. Selectivity characteristics of two-stage 455-kc i-f amplifiers using 6A8, 6K7, 6K7, and 6Q7 tubes. Curve 1, air-trimmed, four-pi universal air-core units; curve 2, single-pi universal permeability-tuned units.

19. Variable Inductors. Probably the simplest form of variable inductor is a tapped winding in which the inductance is varied by taking more or less of the total available winding. This is a step-by-step method of variation and usually not satisfactory. Another form, which is rather bulky, difficult to manufacture, and now little used, is the variometer. This consists of two similar windings so disposed that they are closely coupled and can be changed from a mutual aiding to mutual bucking position in a continuous manner. This is accomplished by placing one winding on the inner surface of a sphere and the other on the outer surface of a slightly smaller sphere within it. The two windings are connected in series. Rotating one sphere with respect to the other gives the desired change in mutual and, hence, in total inductance.

Much more common is the variation of inductance through the variation of the permeability of the core. The effective permeability of the core for a particular inductor is simply the ratio of the inductance with the core in the winding to the inductance with an air core. The effective permeability may be greater than or less than unity, the air-core value. The commonly used windings are solenoid, universal, and progressive universal.

A slug of low-resistance conducting material such as copper will give an effective permeability as low as 1/1.4. This is the result of the eddy currents which are induced in the core. The eddy currents cause flux which always bucks the inducing flux and, hence, reduces the self-inductance.

Copper cores are used at frequencies above about 40 Mc. At such frequencies Qs are relatively high and the decrease in Q caused by the core is not serious. The use of copper cores allows a maximum conductor length since the inductance decreases as the core is inserted. This is mechanically desirable in h-f winding design.

A slug of powdered iron may have an effective permeability as high as 14. Pow-

dered-iron cores are usually used at frequencies lower than 100 Mc. At these frequencies high *Q*s are more important. With high permeabilities, minimum conductor length is required to produce the desired inductance. This means minimum copper losses and, consequently, high *Q*. However, high-permeability cores may have high inherent losses so that the highest over-all *Q* may not be realized with the highest permeability core.

By properly designing a tapered winding, the frequency to which it is tuned by introducing the iron core into the winding can be made linear with linear motion of the core. Furthermore, by the use of such variable-pitch windings, both solenoid and progressive universal types, and by use of movable iron cores, an r-f tuning unit of the two- or three-gang type may be made using permeability-tuned inductors rather than the usual gang capacitors. Such permeability-tuned units can be made small, light, and highly efficient. "Tracking" is accomplished by matched windings and iron cores.

In general, a circuit that contains a permeability-tuned inductor with a stable silvered-mica type of capacitor has far greater frequency stability with time and temperature than a circuit containing a fixed inductor and a variable mica capacitor.

Figure 9 shows the over-all selectivity characteristics of two two-stage 455-kc i-f systems. Curve 1 is that of an air-trimmed, four-pi universal-wound coil system. Curve 2 is that of a single-pi, universal-wound, permeability-tuned coil system. The tubes used in the i-f amplifiers were 6A8, 6K7, 6K7, 6Q7. Despite the fact that less expensive single-pi coils are used, the increased sharpness of resonance due to the use of iron-cored, permeability-tuned units is obvious.

20. Inductor Design. The design of inductors is, for the most part, somewhat more of an art than a science. Many practical factors influence it to such an extent that the theoretically best inductors are not obtainable. Available space, shielding requirements, materials of construction, and cost are usually the controlling factors. Where they are practical, the following formulas for the calculation of inductance are given, but for the most part some examples of the effects of the various variables give a basis for future design work.

The design is somewhat influenced by the end use. However, the principles are the same. It is necessary to stress only the particular characteristic desired in the original design.

Since most inductors now being designed and used in the radio engineering field are for low power applications, as in receiving equipment, the practical data given in this section pertain to such applications. In high-powered transmitting units less thought is given to space and cost, and more thought is given to losses. Most such inductors are designed for single-frequency operation. They may operate at such high power that cooling is necessary. Low-power transmitting inductors are similar to receiving inductors.

CALCULATION OF INDUCTANCE

It is possible to calculate the true (l-f) inductance of some types of air-cored coils with a fair degree of accuracy. *National Bureau of Standards Circular* 74 has long been the most authoritative source of such information. Some of the more useful formulas contained therein are reproduced here.[1] It must be remembered that for r-f inductors the actual apparent inductance differs from the calculated true inductance because of distributed capacitance. For that reason, inductance calculations are generally used only for a starting point in the final design.

In the following formulas all dimensions are expressed in centimeters, and the inductance is in microhenrys.

[1] Rosa, E. B., and F. W. Grover, *Nat. Bur. Standards Sci. Paper* 169; Grover, F. W., *Nat. Bur. Standards Sci. Papers* 320, 1917; 455, 1922; 468, 1923. See for coil design and calculation, especially at low frequencies, Morgan Brooks and H. M. Turner, Inductance of Coils, *Bull.* 53, *Univ. Illinois Eng. Exp. Sta.*, Jan. 8, 1912. Grover, F. W., "Inductance Calculations," Van Nostrand, 1946.

21. Straight Round Wire. If l is the length of the wire, d is the diameter of the cross section, and μ is the permeability of the material of the wire,

$$L_0 = 0.002l\left(\log_\epsilon \frac{4l}{d} - 1 + \frac{\mu}{4}\right) \tag{6}$$

$$= 0.002l\left(2.303 \log_{10} \frac{4l}{d} - 1 + \frac{\mu}{4}\right) \tag{7}$$

If $\mu = 1$ (for all materials except iron),

$$L_0 = 0.002l\left(2.303 \log_{10} \frac{4l}{d} - 0.75\right) \tag{8}$$

The return conductor is assumed to be remote. These formulas give the l-f inductance.

As the frequency increases, the inductance decreases, its value at infinite frequency being

$$L_\infty = 0.002l\left(2.303 \log_{10} \frac{4l}{d} - 1\right) \tag{9}$$

A general expression for the inductance at any frequency is

$$L = 0.002l\left(2.303 \log_{10} \frac{4l}{d} - 1 + \mu\delta\right) \tag{10}$$

The quantity δ is obtained from the table below, as a function of the argument x' where

$$x = 0.1405d\sqrt{\frac{\mu f}{\rho}} \tag{11}$$

and f is the frequency and ρ is the volume resistivity of the wire in microhm-centimeters. For copper at 20°C,

$$x_c = 0.1071d\sqrt{f}$$

This quantity δ will be used in several of the following formulas without further definition.

Value of δ in Inductance Formulas

x	δ	x	δ	x	δ	x	δ	x	δ	x	δ
0	0.250	2.5	0.228	6.0	0.116	12.0	0.059	25.0	0.028	70.0	0.010
0.5	0.250	3.0	0.211	7.0	0.100	14.0	0.050	30.0	0.024	80.0	0.009
1.0	0.249	3.5	0.191	8.0	0.088	16.0	0.044	40.0	0.0175	90.0	0.008
1.5	0.247	4.0	0.1715	9.0	0.078	18.0	0.039	50.0	0.014	100.0	0.007
2.0	0.240	5.0	0.139	10.0	0.070	20.0	0.035	60.0	0.012	∞	0.000

22. Two Parallel Round Wires—Return Circuit. The current is assumed to flow in opposite directions in two parallel wires of length l and diameter d, the distance between centers of wires being D. Then

$$L = 0.004l\left(2.303 \log_{10} \frac{2D}{d} - \frac{D}{l} + \mu\delta\right) \tag{12}$$

This neglects the inductance of the wires connecting the two main wires. If these wires are long, their inductance may be calculated by Eq. (10) and added to the result from Eq. (12), or the whole system may be treated as a rectangle and the inductance calculated by Eq. (14).
FIG. 10. Inductance design chart.

23. Square of Round Wire. The length of one side of the square is denoted by a; other letters have already been defined.

$$L = 0.008a\left(2.303 \log_{10} \frac{2a}{d} + \frac{d}{2a} - 0.774 + \mu\delta\right) \tag{13}$$

24. Rectangle of Round Wire. The sides of the rectangle are a and a_1 and the diagonal $g = \sqrt{a^2 + a_1^2}$. Then

$$L = 0.00921\left[(a + a_1)\log_{10}\frac{4aa_1}{d} - a\log_{10}(a + g) - a_1\log_{10}(a_1 + g)\right] + 0.004\left[\mu\delta(a + a_1) + 2\left(g + \frac{d}{2}\right) - 2(a + a_1)\right] \tag{14}$$

25. Grounded Horizontal Wire. The wire is assumed to be parallel to the earth' which acts as the return circuit. In addition to symbols already used, h denotes the height of the wire above ground. Then

$$L = 0.004605l\left[\log_{10}\frac{4h}{d} + \log_{10}\left(\frac{l + \sqrt{l^2 + \frac{d^2}{4}}}{l + \sqrt{l^2 + 4h^2}}\right)\right] + 0.002\left(\sqrt{l^2 + 4h^2} - \sqrt{l^2 + \frac{d^2}{4}} + \mu l\delta - 2h + \frac{d}{2}\right) \tag{15}$$

Value of K in Eq. (17)

26. Circular Ring of Circular Section. If a is the mean radius of the ring,

$$L = 0.01257a\left(2.303\log_{10}\frac{16a}{d} - 2 + \mu\delta\right) \tag{16}$$

provided that $d/2a \leqslant 0.2$.

27. Single-layer Coil or Solenoid.

$$L = \frac{0.0395a^2n^2}{b}K \tag{17}$$

where n is the number of turns, a is the radius of the coil measured from the axis to the center of the wire, b is the length of the coil, and K is a function of $2a/b$, the value of which may be determined by means of the table above.

28. Multilayer Coils: Circular Coils of Rectangular Cross Section. For long coils of a few layers, the following formula may be used:

$$L = L_s - \frac{0.0216n^2ac}{b}(0.693 + B_s) \tag{18}$$

where L_s is the inductance calculated by Eq. (17), n and b are the same as in Eq. (17), a is the radius of coil measured from axis to center of winding cross section, c is the radial depth of winding, and B_s is the correction given below.

Value of B_s in Eq. (18)

b/c	B_s	b/c	B_s	b/c	B_s	b/c	B_s	b/c	B_s	b/c	B_s
1	0.0000	6	0.2446	11	0.2844	16	0.3017	21	0.3116	26	0.3180
2	0.1202	7	0.2563	12	0.2888	17	0.3041	22	0.3131	27	0.3190

4	0.2076	9	0.2730	14	0.2961	19	0.3082	24	0.3157	29	0.3209
5	0.2292	10	0.2792	15	0.2991	20	0.3099	25	0.3169	30	0.3218

For short multilayer coils, the dimensions shown in Fig. 11 are used. Two formulas are required, one for use when $b > c$, and the other for use when $b < c$. In the first case,

$$L = 0.01257an^2\left[\left(1 + \frac{b^2}{32a^2} + \frac{c^2}{96a^2}\right)\log_\epsilon \frac{8a}{d} - y_1 + \frac{b^2}{16a^2}y^2\right]$$

$$= 0.01257an^2\left[2.303\left(1 + \frac{b^2}{32a^2} + \frac{c^2}{96a^2}\right)\log_{10} \frac{8a}{d} - y_1 + \frac{b^2}{16a^2}y^2\right] \tag{19}$$

Value of Constants in Eqs. (19) and (20)

b/c or c/b	y_1	c/b	y_2	b/c	y_3
0	0.5000	0	0.125	0	0.597

0.60	0.8182	0.60	0.384	0.60	0.702
0.65	0.8265	0.65	0.427	0.65	0.715
0.70	0.8331	0.70	0.474	0.70	0.729
0.75	0.8383	0.75	0.523	0.75	0.742
0.80	0.8422	0.80	0.576	0.80	0.756
0.85	0.8451	0.85	0.632	0.85	0.771
0.90	0.8470	0.90	0.690	0.90	0.786
0.95	0.8480	0.95	0.752	0.95	0.801
1.00	0.8483	1.00	0.816	1.00	0.816

When $b < c$,

$$L = 0.01257an^2\left[\left(1 + \frac{b^2}{32a^2} + \frac{c^2}{96a^2}\right)\log_\epsilon \frac{8a}{d} - y_1 + \frac{c^2}{16a^2}y^3\right]$$

$$= 0.01257an^2\left[2.303\left(1 + \frac{b^2}{32a^2} + \frac{c^2}{96a^2}\right)\log_{10} \frac{8a}{d} - y_1 + \frac{c^2}{16a^2}y^3\right] \quad (20)$$

y_1, y_2, and y_3 may be obtained from the table shown on page 3-19. These formulas are quite accurate as long as the diagonal of the cross section (d, Fig. 11) does not exceed the mean radius. The accuracy decreases considerably as b becomes large in comparison with a.

For very accurate results, a correction must be added if the insulation of the wire occupies a considerable percentage of the winding space. This correction is given by

$$\Delta L = 0.01257an\left(2.303 \log_{10} \frac{D}{d} + 0.155\right) \quad (21)$$

where D is the distance between the centers of adjacent wires, and d is the diameter of the bare wire.

Fig. 11. Multilayer coil.

29. Multilayer Square Coil. If n is the number of turns and a is the side of the square measured to the center of the rectangular cross section which has length b and depth c, then

$$L = 0.008an^2\left(2.303 \log_{10} \frac{a}{b+c} + 0.2235 \frac{b+c}{a} + 0.726\right) \quad (22)$$

If the cross section is square ($b = c$), this becomes

$$L = 0.008an^2\left(2.303 \log_{10} \frac{a}{b} + 0.447 \frac{b}{a} + 0.033\right) \quad (23)$$

Equation (21) may be used to correct for insulation by replacing the factor 0.01257 by 0.008. For a single-layer square coil,

$$L = 0.008an^2\left(2.303 \log_{10} \frac{a}{b} + 0.2231 \frac{b}{a} + 0.726\right) - 0.008an(A + B) \quad (24)$$

Value of A in Eq. (24)

20	0.297	400	0.335
25	0.304	500	0.336
30	0.308	700	0.336
35	0.312	1,000	0.336

A and B are given above, where d is the diameter of the bare wire and D is the distance between turns, measured to the centers of the wires.

30. Calculation of Mutual Inductance.[1] The mutual inductance of two parallel coaxial circles may be calculated by the following method: first, calculate

$$\frac{r_2}{r_1} = \sqrt{\frac{\left(1 - \frac{a}{A}\right)^2 + \frac{D^2}{A^2}}{\left(1 + \frac{a}{A}\right)^2 + \frac{D^2}{A^2}}} \tag{25}$$

where a is the radius of the smaller circle, A the radius of the larger circle, and D the distance between the planes of the two circles. From the table on page 3-22 the value of F corresponding to the calculated value of r_2/r_1 is obtained. Then

$$M = F\sqrt{Aa} \tag{26}$$

The units are the same as in the formulas for self-inductance already given.

For two parallel coaxial multilayer coils of square or nearly square cross section, a good approximation is given by

$$M = n_1 n_2 M_0 \tag{27}$$

where n_1 and n_2 are the numbers of turns on the two coils, and M_0 is the mutual inductance of two circles located at the centers of the cross sections of the two coils.

The same formula may be used as a rough approximation for the mutual inductance of two coaxial single-layer solenoids.

31. Coil Form Relations. From the preceding data it will be seen that for solenoid windings the maximum inductance occurs when the diameter of the winding divided by the length of the winding equals 2.46. For maximum inductance in multilayer solenoids, the winding cross section should be square and the diameter of the form should be about equal to twice the length of a side of that square. For solenoids of the same inductance, the distributed capacitance is approximately proportional to the radius of the form and independent of the number of turns and length of winding.

32. Choice of Wire Size. The choice of wire size for universal windings or progressive universals depends on the desired Q, the permissible outside diameter, and the cost. At the frequencies at which these windings are used, roughly 200 to 2,000 kc stranded wire is desirable to give good Q. In general for a given inductance, the greater the number of strands, the higher the cost and the better the Q. The smaller the strand size, the higher the Q and the cost. The smaller the strand size, the less the outside diameter, a desirable relation with iron cores or where shielding is to be used. The strands should be loosely twisted, about 10 or 12 twists per foot for best results. The effect of wire size on Q, relative cost, and relative outside diameter for a 1-mh winding using some common wire sizes is given in Table 7.

In the region from about 2 to 6 Mc, solenoid windings are used with a wire size of from No. 30 to No. 34. From 6 to 100 Mc, the common wire sizes are from No. 18 to No. 24.

33. Choice of Wire Insulation. There are many insulating materials now in use on wire for fabricating inductors. They fall into two basic groups, the filament or textile type and the coated, dipped, or extruded type. Silk, nylon, du Pont's orlon, celanese, cotton, and glass-fiber filaments are wound around the conductors in either single or double layers to produce the first type. Frequently the conductor has been previously coated with an insulator to prevent short circuits between the turns in case the threads should separate. The purpose of the textile is to facilitate the winding of universal windings or to provide proper spacing between the conductors.

Silk has been very popular but is being replaced by synthetic materials because of its high cost. Cotton gives a very bulky insulation and is used only where considerable conductor spacing is required. The only major r-f coil application is on broadcast-band loop antennas. Orlon winds well but has the disadvantage of poor electrical properties at elevated temperatures which may cause a "runaway" condition resulting in an overheated winding. Glass fiber is difficult to handle and is used only where high temperatures are encountered. Celanese is rather fragile and subject to attack by many of the solvents used in cements and in coil-impregnating materials. It will melt away at soldering temperatures and hence does not have to be removed before soldering.

Nylon-served wire introduces some winding problems since it is both slippery and elastic. However, when properly served and carefully handled, it represents a compromise of properties which explains its current popularity.

Coating materials are oleoresinous varnish, polyvinylformal, nylon, polytetrafluoroethylene, polyurethane, and silicone enamel. Oleoresinous varnish is the traditional plain enamel which has been the most common magnet insulation. Polyvinylformal, better known as "Formvar," was introduced to provide an enamel with greater abrasion resistance. Nylon enamel and, recently, polyurethane enamel, which results from converting isocyanates into resinous compositions, were developed to provide electrical and mechanical properties approaching Formvar but with the added feature of "solderability." These materials melt or decompose at soldering temperatures so that they need not be scraped off before making a soldered joint. Polytetrafluoroethylene, Teflon, either plain or combined with ceramic materials and silicone enamels, was developed for high-temperature applications.

For extremely high temperatures, above 300°F, a completely different approach is being tried. Copper wire is electrocoated with aluminum. The aluminum is then anodized to provide an insulating film.

It should be remembered that the insulation on wire is a necessary evil. It should be omitted wherever possible, *e.g.*, in spaced solenoids wound on threaded forms. In any case it should be kept to the practical minimum.

34. Choice of Form. Form size is dictated by space limitations, winding type, winding design, and cost. The important factor left to consider is material. It must be strong enough to support the winding and, since it is usually largely within the field of the winding, it must be electrically good. It should be dimensionally stable with temperature changes. No material yet known is electrically perfect and, therefore, the less form material used, the less additional losses will be introduced.

Common materials are ceramics, such as steatite, thermosetting plastics, such as molded or laminated phenolics, thermoplastics, such as polystyrene and its copolymers, cellulose acetate and its copolymers, ethyl cellulose, glass, fiber, and paper.

Ceramics and glass are good electrically but are fragile and cannot be made to close dimensional tolerances. As a group they are the most expensive. The phenolics vary widely in their electrical properties depending on the filler used. The better electrical grades are satisfactory and are mechanically better and less costly than ceramics. Certain of the plastics, particularly the styrenes and ethyl cellulose, have the best electrical properties but are not too widely used because they will not stand the rather high temperatures encountered in modern receivers. This is particularly true when the winding has appreciable tension.

Fiber and paper are economical. When properly treated with wax, these materials are suitable for all but the most exacting applications.

Certain windings are completely self-supporting and require no form. Others are wound directly on powdered-iron cores.

35. Choice of Finish. The finish on an inductor performs two major functions: it helps to make the unit mechanically stable and to make it electrically stable through protection against ambient conditions. The most common finishes are waxes, varnishes, and lacquers, or synthetics. The choice of finish depends on the conditions to be encountered and on the amount of additional losses that can be tolerated in the final design. The use of any finish always introduces some loss.

Operating temperatures may range from −20 to +160°F for civilian broadcast units. The rigorous demands of high-performance aircraft, guided missiles, and satellites extend the range from −70 to +300, 400, and even 1000°F. At these temperatures the units may also be subjected to high values of shock and vibration. Relative humidities may vary over a wide range.

Waxes, particularly the microcrystalline type, ceresins, etc., are excellent for the moderate temperatures of civilian use. They are simple to use, are inexpensive, have fairly low losses, and low dielectric constants, are noncorrosive, and provide the best humidity protection. They should never be used when the ambient temperature is close to their melting point.

Varnishes, both the solvent and solventless types, are usually not so good electrically, particularly at the higher frequencies. The initial expense and cost of application are high. The common heat polymerizing varnishes have a short shelf life before use. However, properly applied varnishes give good humidity protection, withstand a greater temperature range than waxes, and are mechanically strong.

Lacquers or synthetics are easier to apply than varnishes, give about as good mechanical strength, have lower losses, but do not give so good humidity protection. They can be made so that they have low dielectric constants. This fact is important since any finish becomes a part of the dielectric of the distributed capacitance; in many designs it is a large part.

In choosing a finish the following points are important: (1) the temperature range. The finish must hold the windings firmly throughout the operating temperature range. It must not change physically with temperature changes for that would distort the

winding. It must not change its dielectric constant since that would change the apparent inductance. (2) The finish should be as good a dielectric as possible so that the losses will be kept to a minimum. The dielectric constant must be low to keep the distributed capacitance low. (3) The finish should afford good humidity protection and at the same time be noncorrosive. Since many inductors have d-c potentials applied and are wound with fine wire or stranded wire, any tendency for corrosion would be accelerated and quickly result in an open circuit.

Accelerated corrosion tests can be made with typical universal windings spaced ¼ in. apart, wound with 7/41 SSE litz wire, subjected to 90 to 95 per cent relative humidity at 100 to 120°F, with 400 volts d.c. between the windings. Under these conditions, windings treated with practically any lacquer or varnish show at least one and at most seven strands of the litz completely corroded after 96 hr. Wax-treated units in the same test rarely show more than one broken strand and usually not any.

36. Methods of Obtaining Close Coupling. For universal windings, close coupling is obtained by making the second winding a continuation of the first, sometimes separated by a layer of tape. The two windings may be placed side by side very close together. In some cases maximum coupling has been obtained by bifilar winding in which two conductors are wound simultaneously and are always parallel as the winding is built up.

For solenoids bifilar winding is also used. Less coupling is obtained by interwinding only a part of the two windings. The second winding may be placed directly over the first, separated by a tape.

Similar methods apply to other types of windings. Where powdered-iron cores are used, close coupling can be obtained by simply winding both coils on the same iron. Such practice is not recommended unless high-resistance iron is used.

Coupling as high as 98 per cent can be obtained with bifilar universals and as high as 90 per cent with bifilar solenoids. The use of iron cores in the windings and iron cups surrounding the windings will increase the coupling in most cases.

37. Effect of Shielding. To prevent undesirable coupling between inductors it is common to surround them with a shield of conducting material. The best conductor is copper and, although it is sometimes used, it is expensive and requires some treatment to maintain its appearance. Easy to fabricate, light in weight, low in cost, and requiring no treatment, aluminum is a favorite shield material. Zinc is also used, especially when it is necessary to soft-solder to the shield.

Shielding is accomplished because of the eddy currents set up in the conducting material. The eddy currents oppose the inducing flux and, therefore, repel and confine it. This opposition to the flux acts as a negative permeability of the surrounding medium. Because the shield is not a perfect conductor, losses are introduced that reflect as losses in the inductor. Shielding lowers the inductance and the Q. The proximity of the shield to the inductor and the shield material controls the amount of lowering that takes place.

Shielding is also accomplished through the use of cups or sleeves of powdered iron. In this case the flux is concentrated in the low-reluctance path of the iron. The Q and inductance of the winding may be slightly increased. This type of shielding is not complete, and usually the whole is surrounded with a conventional aluminum shield, which then has little effect on the winding. Its function is to provide electrostatic shielding for more complete shielding.

38. Special Considerations in the Use of Powdered-iron Cores. The use of powdered-iron cores materially changes some details of winding design. It is most important to get as much of the winding as possible as near the core as possible. In so doing the maximum number of turns of the conductor is affected by the core. In other words, there is less leakage flux and more active flux to produce the maximum inductance.

In the case of universal windings, the depth of the winding should be kept to a minimum to keep the average turn closer to the core. In all cases, the less the wall thickness of the form used, the better the results.

39. Typical Inductors Currently in Use. The following inductors are used in a typical broadcast receiver employing a loop antenna. The set has a standard 365-$\mu\mu$f three-gang variable capacitor. All inductors are impregnated and flashed in wax. Shields used for r-f coil, first and second i-f coils, are all 1¼-in.-square aluminum, 2½ in. long.

Loop Antenna.

Wound in the form of a flat spiral, elliptical in shape, minor diameter of average turn = 5 in., major diameter of average turn = 11 in., wire = 22 DCE, Q at 1 Mc = 149 far from chassis and 72 mounted on chassis, turns = 27, inductance = 265.7 μh, C_d = 16.8 $\mu\mu$f.

R-f Coil.

Type	Turns	Width, in.	Wire	Air inductance	Q in shield at 1 Mc
Primary universal	646	13/64	39 SSE	6.38 mh	
Secondary 4-layer bank	195	....	7/41 SSE	280 μh	98

Spacing primary to secondary 5/64 in. L_M = 200 μh. Form: ½ in. OD by 7/16 in. ID, bakelite.

Oscillator Coil.

Type	Turns	Width, in.	Wire	Air inductance, μh
Primary universal	23¾	3/16	36 SCE	14
Secondary universal	83¼	3/16	36 SCE	127

Secondary wound on top of primary separated by yellow cambric ⅜ by 0.010 by 211/16 in. L_M = 25.1 μh in air. Form: ½ in. OD by ⅜ in. ID, wax-impregnated paper.

First I-f Transformer.

Type	Turns	Width, in.	Wire	Air inductance, mh	Q in shield at 455 kc
Primary universal	422	3/16	5/42 SSE	2.27	83
Secondary universal	422	3/16	5/42 SSE	2.27	82

Spacing primary to secondary 9/16 in. L_M = 109.2 μh in air. Form: ⅜ in. OD by 5/16 in. ID, wax-impregnated paper.

Second I-f (Diode) Transformer.

Type	Turns	Width, in.	Wire	Air inductance, mh	Q in shield at 455 kc
Primary universal	365	3/16	5/42 SSE	1.7	90
Secondary universal	415	3/16	5/42 SSE	2.2	83

Spacing, primary to secondary, 39/64 in. L_M = 130.7 μh in air. Form: ⅜ in. OD by 5/16 in. ID, wax-impregnated paper.

The following inductors are used in a typical permeability-tuned automobile broadcast receiver covering 535 to 1,610 kc.

Antenna and R-f Coils.

Form: 0.223 in. OD by 0.207 in. ID, bakelite. 356 turns 5/43 SSE straight progressive universal winding 1 1/4 in. long. Minimum Q = 60 at 600 kc. Core: 0.200 in. OD by 1 1/2 in. long. Apparent permeability = 9. Lacquer-coated. These coils tune to 1,610 kc with 65 μμf, no core.

Oscillator Coil.

Form: 0.318 in. OD by 0.207 in. ID, bakelite. 140 turns 36 E. Variable-pitch solenoid, 1 9/32 in. long. Core same as for antenna and r-f coils. Lacquer-coated. This coil tunes to 1,870 kc with 196 μμf, no core. Cathode coil wound on 7/16 in. OD by 3/8 in. ID bakelized paper. Winding: 16 turns of No. 30 E at 13 turns per inch. This coil is slipped over the oscillator winding and exactly centered over it.

The i-f transformers used in this receiver are listed as "auto set" transformers in Table 13. The transformers in this table all have the same basic construction. All have 3/4-in.-square aluminum shields, 0.283-in.-OD phenolic-impregnated tubing, threaded to receive 1/4 in. by 28 pitch, powdered-iron screw cores and, where required, silvered-mica capacitors.

Table 13. Typical Receiver Inductors

NOTES:
Frequency: 1–262 kc, 2–4.5 Mc, 3–44 Mc, 4–41.25 Mc.
Type of winding: 1, universal; 2, solenoid.
Core: 1, Plast-iron B214; 2, Carbonyl TH; 3, Carbonyl L; 4, Carbonyl C; 5, Carbonyl J; 6, IRN8.
Wire: 1, No. 40 SNE; 2, No. 38 SNE; 3, No. 36 SNE; 4, No. 2/41 SNE; 5, No. 36 E; 6, No. 34 E; 7, No. 30 E; 8, No. 22 E.
Tpi is turns per inch for solenoid windings.
C/T is crosses per turn for universal windings.
CW is close-wound.

Part 2: MAGNETIC MATERIALS[1]

Magnetic materials are essential in the construction of nearly all types of electrical machinery and apparatus. In the field of radio communication, they are employed in the cores of transformers, choke coils, relays, etc., and for magnetic shielding. Permanent magnets are used in d-c measuring instruments, polarized relays, magnetrons, and loud-speakers. A great variety of magnetic materials is produced commercially, and new types are continually being developed. In view of the diversity in requirements for practical applications, a knowledge of the magnetic characteristics of available materials is needed in connection with the design of various types of appa-

[1] The material for this portion of Chap. 3 came in part from "Permanent Magnets" and "Magnetic Testing," *Nat. Bur. Standards Circ.*, C448 and C456.

ratus. The principal producers of magnetic materials issue technical data giving the properties of the materials they make. Before undertaking the design of apparatus involving the use of magnetic materials it is best to obtain up-to-date information from one or more of these manufacturers.

MAGNETIC QUANTITIES AND UNITS

The characteristics of magnetic circuits and the magnetic materials of which they are made are expressed in terms of certain magnetic quantities and units which may be described as follows:[1]

40. Magnetomotive Force. Magnetization is generally accomplished by means of electric current in windings linked with a magnetic circuit of which the material to be magnetized forms a part. The total measure of the magnetizing effect of such a coil is called the magnetomotive force, $\mathfrak{F}$. The cgs unit of magnetomotive force (mmf) is called the *gilbert* and is defined by the equation

$$\mathfrak{F} = 0.4\pi NI$$

where $\mathfrak{F}$ = mmf, gilberts
N = number of turns in the coil
I = current, amp

41. Magnetic Flux. The total measure of the magnetized condition of a magnetic circuit when acted upon by a magnetomotive force is called the "magnetic flux," ϕ. It is characterized by the fact that a variation in its magnitude gives rise to an emf in an electric circuit linked with it. The emf thus induced is at any instant directly proportional to the time rate of variation of the flux. The cgs unit of magnetic flux is called the *maxwell* and is defined by the equation

$$e = N\left(\frac{d\phi}{dt}\right)10^{-8}$$

where e = induced emf, volts
N = number of turns linked with the flux
ϕ = magnetic flux, maxwells
t = time, sec

42. Magnetic Reluctance. That property of a magnetic circuit which determines the relationship between the magnetic flux and the corresponding mmf is called the "magnetic reluctance," $\mathcal{R}$, of the circuit. The cgs unit[2] is defined by the equation

$$\phi = \frac{\mathfrak{F}}{\mathcal{R}}$$

where ϕ = magnetic flux, maxwells
$\mathfrak{F}$ = mmf, gilberts
$\mathcal{R}$ = magnetic reluctance in cgs units

In a magnetic circuit of uniform cross-sectional area and uniform permeability (to be defined later),

$$\mathcal{R} = \frac{l}{\mu A}$$

where $\mathcal{R}$ = magnetic reluctance in cgs units
μ = magnetic permeability
l = length, cm
A = cross-sectional area, sq cm

[1] Although some of these definitions are not mathematically rigorous, they are essentially correct and somewhat easier to understand than the more rigorous forms would be.

[2] The unit of magnetic reluctance was called the "oersted" until 1930, when the International Electrotechnical Commission adopted that name for the unit of magnetizing force, thus leaving the unit of reluctance without a name.

43. Magnetic Permeance. Magnetic permeance, $\mathcal{P}$, is the reciprocal of the magnetic reluctance. Thus,

$$\phi = \mathcal{F}\mathcal{P}$$

where ϕ = magnetic flux, maxwells
$\mathcal{F}$ = mmf, gilberts
$\mathcal{P}$ = magnetic permeance in cgs units

In a circuit of uniform cross section and permeability

$$\mathcal{P} = \frac{\mu A}{l}$$

44. Magnetizing Force. The mmf acting on a magnetic circuit is distributed along its length in a manner determined by the distribution of the magnetizing winding and of the reluctance of the circuit. The mmf per unit length along the circuit is called the "magnetizing force," H. The cgs unit is called the *oersted* and is defined by the equation

$$H = \frac{d\mathcal{F}}{dl}$$

where H = magnetizing force, oersteds
$\mathcal{F}$ = mmf, gilberts
l = length, cm

At the center of a very long, uniformly wound solenoid having n turns per cm in which there is a current of I amp, the magnetizing force in oersteds is

$$H = 0.4\pi nI$$

45. Magnetic Induction. Magnetic induction, B, also called "magnetic flux density," is the magnetic flux per unit area of a section normal to the direction of the flux. The cgs unit is called the *gauss* and is defined by the equation

$$B = \frac{d\phi}{dA}$$

where B = magnetic induction, gausses
ϕ = magnetic flux, maxwells
A = area, sq cm

46. Intrinsic Induction. That part of the magnetic induction which is in excess of the induction that would exist in a vacuum under the influence of a given magnetizing force is called the "intrinsic induction," B_i. Numerically, in the cgs system $B_i = B - H$.

47. Nature of Magnetism. It is generally conceded that the only known source of magnetic effects is electricity in motion (electric current). According to present theory,[1] ferromagnetic effects are due to groups of electrons within a ferromagnetic material called "domains" and consisting of electrons spinning on their own axes. The magnetic axes of the spinning electrons in a single domain are held parallel to each other by mutual forces known as "exchange forces," so that each domain behaves as a single unit. The domains are in effect current-turns and so account for the mmfs inherent in ferromagnetic materials. The sum total of the mmfs due to the domains is the quantity that remains "permanent" in a permanent magnet.

In the unmagnetized condition, the domains are so oriented with respect to each other that the net magnetic effect is zero in any direction. Under the influence of a magnetic field applied by means of an external electric current, the magnetic axes of the domains tend to be oriented more or less in the direction of the applied field, so that their effect is added to that of the applied field. The flux density due to the combined effect of the applied field and the domains is the magnetic induction, B, and that due to the domains alone is the intrinsic induction, B_i.

[1] Bozorth, R. M., "Ferromagnetism," p. 423, Van Nostrand, 1951.

Upon removal of the magnetizing force, the orientations of the domains resulting from the applied field tend to persist to a greater or less extent, depending upon their distribution in space, which in turn depends upon the internal structure of the material. To reduce the induction further, it is necessary to apply a reverse, or demagnetizing, force. The relationships between induction and the applied field are shown graphically in Fig. 12, where the abscissas represent values of magnetizing force, H, and the ordinates are values of magnetic induction, B. The curve *oabc* is called the "normal induction curve" and shows how the induction varies as the magnetizing force applied to a material initially in the demagnetized condition is increased from zero. At any point on this curve, the ratio of the value of induction to the corresponding value of magnetizing force is called the *magnetic permeability*, μ. Thus the coordinates of point a on the curve are B_a and H_a, respectively, and the permeability is

$$\mu = \frac{B_a}{H_a}$$

Fig. 12. Normal induction and hysteresis curves.

Since the line *oabc* is not straight, the permeability is not constant but varies with the degree of magnetization. This variation is one of the distinguishing characteristics of ferromagnetic materials.

48. Hysteresis Effects. If, after the magnetizing force has reached a certain value (as at point b), it is then decreased the induction does not follow the curve *oabc* in reverse order but lags behind the magnetizing force, as shown by the curve *bd*. Thus, when the magnetizing force has been reduced to zero, point d, the induction still has an appreciable value. This value is called the *residual induction*, B_r.

To reduce the induction still further, it is necessary to increase the magnetizing force in the opposite direction. The value of the reversed magnetizing force required to reduce the induction to zero is called the *coercive force*, H_c.

The lagging of the induction behind the magnetizing force is called *hysteresis*, and the complete curve *bdefghb*, is called a hysteresis "loop." Hysteresis is another of the characteristics of ferromagnetic materials and is the property that makes permanent magnets possible. The size of the hysteresis loop, and consequently the magnitudes of B_r and H_c, depends upon the values of B and H at the tip of the loop, generally designated by the symbols B_m and H_m. As H_m is increased, the size of the hysteresis loop approaches a maximum. The values of B_r and H_c corresponding to the maximum loop for a given material are called the *retentivity* and *coercivity*, respectively.

A major hysteresis loop is produced by varying the magnetizing force continuously from a positive maximum value to the same value negative and back again to the positive maximum. However, if a change in direction of the variation is made at some intermediate point on the major loop, a minor loop is produced, as shown between the points i and k in Fig. 12. The slope of the line joining the tips of such minor loops is called the *incremental permeability*, μ_Δ. In other words, the incremental permeability is the ratio of the change in B to the corresponding change in H when the average value of B differs from zero. That is, $\mu_\Delta = \Delta B/\Delta H$.

That part of the hysteresis loop extending from the residual induction, B_r, to the coercive force, H_c, *i.e.*, from d to e, is called the *demagnetization curve*. Points on this
curve are designated by the coordinates B_d and H_d. Most of the important characteristics of a permanent-magnet material can be indicated by points on this curve or within the area between it and the axes of coordinates. The value of H_m necessary to produce the maximum loop depends upon the type of material and ranges from about 300 oersteds for most of the older types of material to about 3,000 oersteds or more for the newer types. Figure 13 represents a typical demagnetization curve, together with the so-called *energy-product* curve obtained by plotting the product of corresponding values of B_d and H_d on the demagnetization curve against B_d. The maximum value of this product, $(B_dH_d)_{max}$, can be considered as a criterion of quality and is useful for the comparison of various materials. It is generally not necessary to plot the B_dH_d curve to determine the maximum energy product. A line drawn from the origin of coordinates to the intersection of horizontal and vertical lines through B_r and H_c, respectively, intersects the demagnetization curve at the point where the product B_dH_d is a maximum for most materials.

FIG. 13. Demagnetization and energy-product curves.

MAGNETIC CHARACTERISTICS OF MATERIALS

Magnetic materials employed in commercial practice may be considered under the following classifications: (1) solid-core materials, (2) electrical sheet and strip, (3) special-purpose alloys, (4) permanent-magnet alloys.

49. Solid-core Materials. These materials are used for the cores of d-c electromagnets, relays, field frames of d-c machines, etc. The principal requirement is high permeability, particularly at relatively high induction. For most uses it is also desirable that the hysteresis be low. The principal materials employed are soft iron, relay steel, cast steel, cast iron, and an alloy of approximately 35 per cent of cobalt and 65 per cent of iron known as ferrocobalt. Ferrocobalt is characterized by very high permeability in the upper part of the normal induction range and a saturation induction approximately 10 per cent greater than that of pure iron. Its cost is relatively high, however, and its use is limited in general to pole pieces in which a very high induction is required. Cast iron has a relatively low permeability and is used principally in field frames when cost is of primary importance and extra weight is not objectionable. Several varieties of soft iron are available, such as Norway iron, Armco iron, and Swedish charcoal iron. Relay steels contain from 1 to 3.25 per cent of silicon to reduce aging. Electrolytic iron may also be used. All these materials are relatively pure iron, low in carbon and other impurities. Cast steel should be low in carbon, not over 0.1 to 0.2 per cent, and contain only the usual small amounts of the ordinary impurities. Cast iron is high in carbon, about 3 per cent, and also contains about 3 per cent of silicon and varying percentages of phosphorus, manganese, and sulfur.

The best magnetic properties are obtained by a suitable annealing treatment. The properties of cast iron can be greatly improved by malleableizing, a process that converts a large part of the carbon to the amorphous form.

50. Electrical Sheet and Strip. The terms *electrical sheet* and *electrical strip* are commonly used to designate silicon-iron alloys produced in sheet or strip form and used as core materials in a-c apparatus, such as transformers, generators, motors, electromagnets, or relays. The principal requirements are high permeability, low hysteresis, and high resistivity. The several grades differ mainly with respect to their silicon content, which ranges from about 0.5 per cent to approximately 4.5 per
cent. Alloys containing the higher percentages of silicon are practically nonaging; *i.e.*, the permeability and losses do not change with time. The required magnetic properties are produced by annealing.
FIG. 14. Typical normal induction curves for solid-core materials.
FIG. 15. Typical normal induction curves for electrical sheet.

By a suitable combination of cold-rolling and heat-treatment, materials are produced in which the crystal axes are given a definite orientation. Such material has considerably better properties, when magnetized in the preferred direction, than the ordinary grades. Figure 15 shows typical normal induction curves for two grades of

electrical sheet and oriented-grain material. The improvement in the oriented-grain material is particularly conspicuous in the upper part of the normal induction curve.

The different grades of electrical sheet and strip are usually sold on the basis of guaranteed maximum values of total core loss, as determined in accordance with the specifications of the ASTM.[1] The common designations of the various grades

[1] "Ferrous Metals," latest ed., ASTM Standards.

are armature, electrical, motor, dynamo, and transformer. The transformer grades are further subdivided into classes denoted by numerals corresponding to the core loss under standard conditions. Armature, electrical, and motor grades are used principally in small motors, a-c magnets, and starting transformers. The dynamo grade is used in high-efficiency rotating machines and small transformers. The transformer grades are used in power and radio transformers (see Table 14).

51. Special-purpose Alloys. For certain applications, special alloys have been developed which, after proper heat-treatment, have superior properties in certain ranges of magnetization. For instance, alloys of nickel and iron with possible small percentages of molybdenum or chromium have very high values of initial and maximum permeability. Alloys of this class, which may have from 70 to 80 per cent of nickel, are called "permalloys." An alloy of 50 per cent of nickel and 50 per cent of iron is called "hipernik." Another alloy having a small percentage of copper in its composition is called "mumetal." The characteristics of these alloys differ in detail, but in general they have high initial and maximum permeability, low hysteresis, and low saturation values. They are particularly applicable for use at low inductions. Typical permeability curves are given in Fig. 16.

Fig. 16. Typical permeability curves for special-purpose alloys.

A certain alloy of nickel, cobalt, and iron after suitable heat-treatment has very nearly constant permeability for inductions below 1,000 gausses and is called *perminvar*. The 50–50 nickel-iron alloy can also be heat-treated so as to have similar characteristics.

An alloy of equal proportions of iron and cobalt has high permeability which persists at higher values of induction than the nickel-iron alloys and is called *permendur*.

Table 15. Typical Characteristics of Some Special Magnetic Alloys*

Alloy	Nominal composition, per cent†	Initial permeability, μ_0	Max permeability, μ_m	Coercive force, H_c	Saturation induction, B_s	Resistivity, microhm-cm	Density, g/cm³

* Subject to some variation in actual practice.
† Balance iron plus usual small amounts of impurities.

Typical characteristics of some special magnetic alloys are given in Table 15.

In recent years, the increasing use of apparatus such as saturable-core reactors, magnetic amplifiers, and the like, which for best operation require materials having hysteresis loops as nearly rectangular as possible, has brought about the development

of a new series of materials.[1] Although the oriented-grain materials previously mentioned have this characteristic to a certain degree, the iron-nickel alloys, when given certain mechanical, thermal, and sometimes magnetic treatments are found to have superior qualities. Not only do they have nearly rectangular hysteresis loops but also their initial and maximum permeabilities are considerably higher.

One caution should be suggested at this point. Data given by producers in published tables generally relate to the static properties of the materials. However, it has been found that the so-called "dynamic" hysteresis loops obtained at frequencies even as low as 60 cps are considerably wider than the static loops. It is always best to check with the producer on this point before deciding on a final design. This is a good general rule because magnetic materials are undergoing continuous development and new and superior materials for a particular purpose may become available at any time.

Another series of magnetic alloys of copper, nickel, and iron is temperature-sensitive, having an approximately linear relation between permeability and temperature. These are called "thermalloys." The principal use is in the compensation of watt-hour meters for temperature variations. They are also used in certain types of thermal relays.

Table 16. Typical Characteristics of Some Commercially Available Ferrites

Nominal composition, %	Saturation induction B_s	Initial permeability μ_0 at 1 Mc	Max permeability μ_m	tan δ_m*	Curie point, °C
10NiO, 23ZnO	1,800	1,000	4,300	0.0022	70
10NiO, 24ZnO	2,400	960	2,700	0.0024	100
16NiO, 17ZnO	3,600	520	1,480	0.0009	140
16NiO, 17ZnO	3,100	330	730	0.0009	260

* $\tan \delta_m = 1/Q = R/\omega L = \omega CR$.

52. Ferrites. The principal disadvantage of the sheet and strip materials for high-frequency applications is their relatively low electrical resistivity. In recent years, a new type of material having very high resistivity has been developed. Several materials of this type are commercially available which not only have high resistivity but also have usable magnetic properties. They are ceramiclike materials whose composition may be represented by the formula $xMO \cdot Fe_2O_3 + yM'O \cdot Fe_2O_3$, where M and M' are bivalent metals and $x + y = 1$. The metals most commonly used are nickel, zinc, and manganese. Small amounts of copper, magnesium, or silicon may also be present. These materials are usually called ferrites. Their structure is of the type called spinel. Harvey, Hegyi, and Leverenz[2] have coined the name "ferro-spinel," which seems to be more appropriate because the term "ferrite" is well established as denoting practically pure iron when it is one of the constituents found in ferrous alloys.

The process of manufacture involves mixing the powdered components (oxides) in definite proportions, compressing the mixture into the desired shape, and sintering (not melting) at a high temperature. The mixed components react and diffuse to form the desired spinel structure.

[1] Trade names by which these materials are designated include Deltamax, Permanorm, Permeron, Orthonol, and Orthonik.

[2] Harvey, R. L., I. J. Hegyi, and H. W. Leverenz, Ferromagnetic Spinels for Radio Frequencies, *RCA Rev.*, **11**, 321, 1950.

Table 16 gives some typical characteristics of a few commercially available ferrites. However, materials of this type are undergoing continuous development and much improved properties can confidently be expected. It will be noted that the Curie point for these materials is low. This limits the temperatures at which they can be operated.

53. Permanent-magnet Alloys. For permanent magnets, high values of residual induction and coercive force are required. Ordinary high-carbon steels and some special tool steels make fair magnets when properly hardened, but better results are obtained by the use of alloys specially made for the purpose. Development along this line has been rapid during the past few years and is still going on. There are at present three general classes of permanent-magnet materials: those in which the principal alloying elements are tungsten or chromium or both; those in which cobalt is present in substantial amounts; and those in which aluminum and nickel play an important part.

Tungsten, chromium, or cobalt magnet steels are hardened by quenching. The aluminum-nickel alloys are among the so-called dispersion-hardening alloys, the final

Table 17. Typical Characteristics of Several Permanent-magnet Alloys[a]

Type	Nominal composition[b]	Residual induction, B_r	Coercive force, H_c	$(B_dH_d) \times 10^{-6}$	Fabrication[c]
Tungsten	5.5W, 0.6C	10,000	65	0.27	Hot-forge or cast, machine
3½% Cr	3.5Cr, 0.3Mn, 0.9C	9,500	63	0.25	Hot-forge or cast, machine

treatment for which is prolonged heating at a temperature of the order of 660 to 700°C. The alloys that are hardened by quenching can be forged and machined, but most of the dispersion-hardening alloys cannot be forged or machined and must be cast to shape and can be cut only by grinding.

The important magnetic characteristics of permanent-magnet alloys are indicated by the part of the hysteresis loop lying between the residual induction and the coercive force and a curve plotted between B and the products of corresponding values of B and H for the same part of the loop. These products are proportional to the magnetic energy stored at the given values of induction. The maximum value of the energy product may be taken as an index of magnetic quality. Typical curves for the three classes of permanent-magnet material are shown in Fig. 17.
FIG. 17. Demagnetization and energy-product curves for typical magnet materials.

The choice of material for a given application depends upon several factors and, consequently, no one material can be considered as best under all conditions. (See Table 17 for typical characteristics of several permanent-magnet alloys.)

MAGNETIC TESTING

According to the use for which magnetic materials are intended, testing is done by either d-c or a-c methods. In some cases, a material may be subjected to both kinds of test. In the United States, magnetic testing is usually carried out in accordance with the specifications of the American Society for Testing Materials.[1] Since these specifications are modified from time to time to keep pace with the continued improvements in magnetic materials, it is always advisable to consult the latest edition if one contemplates entering the field of magnetic testing. No attempt will be made to describe in detail the techniques involved in magnetic testing as these are to be found in the ASTM specifications. However, there are certain general principles which underlie all techniques and apparatus and which may be of general interest.

54. Tests with Direct Current. The methods and apparatus currently approved as standard by the ASTM for d-c magnetic testing include the Rowland ring method,[2] the Burrows compensated double yoke,[3] the MH permeameter,[4] the Fahy Simplex permeameter,[5] the High-H permeameter,[6] the Babbitt permeameter,[7] the Simplex super-H adapter,[8] and the Saturation permeameter.[9] Some producers have adopted certain nonstandard methods which are simpler and easier to operate and are sufficiently consistent to be used for quality control.

The d-c methods listed above are called ballistic methods because they employ ballistic galvanometers (or fluxmeters) in the measurements. Figure 18 is the basic diagram of connections for ballistic tests. The differences between different methods lie in the type of magnetic circuit employed and the arrangement of the magnetizing and test coils. In some types of apparatus, for example, the coil L_2 is located near the surface of the specimen (designated as T in the diagram) and is used to measure the magnetizing force. In other methods such as the Rowland ring or the Burrows compensated double yoke this coil is absent and the magnetizing force is measured in terms of the current in the primary winding. *BG* represents the ballistic galvanometer. The diagram shows alternative ways of connecting the galvanometer. In the one at the right, R_p is the resistance required for critical damping. Some operators prefer this connection. The mutual inductor M_1M_2 is used to calibrate the galvanometer. An excellent treatment of the theory and use of the ballistic galvanometer is given by Harris.[1]
FIG. 18. Connections for ballistic test.

55. Tests with Alternating Current. Several a-c tests for the determination of core loss, a-c permeability, and incremental permeability are specified by the ASTM but some a-c tests required for materials used at higher-than-power frequencies have not at this writing been standardized by the society. However, work is in progress and standard methods should become available in the near future.

Figure 19 shows the basic circuit for the measurement of core loss and a-c permeability on flat-rolled materials. For several years the standard sample was made up of strips 3 cm wide and 50 cm long. The sample weighed 10 kg. These strips were assembled in four equal bundles and inserted in the four coils of an "Epstein" test frame with butt joints at the corners. The coils consisted of two windings, a primary winding and a secondary winding having equal numbers of turns uniformly distributed on the coil forms. In later years, the 50-cm sample has been replaced for the most part by the so-called 25-cm Epstein test. The samples for this test originally consisted of strips 25 cm long and arranged in the test frame to have alternate butt and lap joints at the corners. The present standard specifies double-lap joints and consequently a length of at least 28 cm is required. For details of procedure, for this test, the latest specifications of the ASTM should be consulted.

[1] Harris, F. K., "Electrical Measurements," Wiley, 1952.

One of the permeameters which has not yet been standardized by the ASTM is the radio-frequency permeameter described by Haas.[1] It is a modification of a permeameter originally described by Kelsall[2] for a-c measurements at small magnetizing forces. The instrument was designed primarily for testing toroidal cores without the necessity of placing a winding on each individual core. By an ingenious construction, it is possible to insert a toroid in the instrument and then to surround the core by a single-turn coil by means of a cover plate. The specimen with its single-turn winding then constitutes the secondary of a transformer. The measurements are made in terms of the influence of the sample on the measured impedance of the primary winding of the transformer. The measuring instrument is usually an impedance bridge or a Q meter. Measurements of initial permeability and dissipation factor can be made by this instrument at radio frequencies up to 20 Mc.
FIG. 19. Circuit for core-loss and a-c permeability tests.

For determining the "dynamic" hysteresis loops, several circuits involving the use of cathode-ray oscilloscopes have been developed. Some of these have been described by Wiegand and Hansen,[3] Zemsky,[4] and others.

56. Tests of Permanent Magnets. The testing of permanent-magnet materials for determining their demagnetization curves is pretty well standardized[5] and need not be discussed here. However, there are some principles involved in the testing of finished magnets that merit some consideration.

It is a quite common practice to judge the strength of a magnet roughly by the force of attraction between it and a piece of soft iron. If the purpose for which the magnet is to be used is to attract or hold an armature, this is a logical method of test, and the attractive force may be measured quantitatively for the purpose of comparing magnets of the same size and shape. However, if the magnet is to be used for any other purpose, the application of such a test may not only give unsatisfactory results but also may prove to be detrimental to the magnet. The characterization of a permanent-magnet material by stating the weight a magnet can lift as related to its own weight is usually misleading, because this relationship is a function not only of the magnetic quality of the material but also of the size and shape of the magnet and the nature of the contact between the magnet and the mass lifted.

Magnets are customarily tested by either one of two methods. One method consists in determining the flux in the neutral zone by quickly removing a test coil con-

[5] Sanford, R. L., Magnetic Testing, *Nat. Bur. Standards Circ.* C456, 1946.

nected to a ballistic galvanometer or fluxmeter. The other method consists in determining the field strength in the gap of special pole pieces to which the magnet is applied. The field strength may be measured in terms of the deflection of a pivoted coil in which a definite current is flowing, the emf induced in an armature rotated at a definite speed, or by a test coil and ballistic galvanometer. A bismuth spiral might also be used, but this is less satisfactory than any of the other methods.

Unless the special pole pieces have the same permeance as the pole pieces to which the magnet is to be applied in use, neither of these methods duplicates the conditions under which the magnet is to function and, consequently, the results must be interpreted with care. If the magnet is designed in such a way as to require magnetization with pole pieces in place, with subsequent magnetic stabilization by partial demagnetization, it will be necessary to remagnetize after testing. Otherwise, the required strength will not be obtained in the finished apparatus. Furthermore, a single test will give no indication of whether or not the magnet has been properly aged. Thermal stabilization must be applied to the finished apparatus after all other treatments have been applied, and tests as to its effectiveness must be made by temperature tests on the finished apparatus.

57. Applications. The principal applications involving the use of magnetic materials in radio or other electronic devices are (1) electromagnets, (2) transformers and inductors, (3) permanent magnets.

1. The principal application of electromagnets is in relays.[1] Unless a relay is to be operated with a.c., the core material is usually of solid material. If a.c. is used, the core must be laminated to minimize the demagnetizing effect of induced eddy currents. There are many types of relay in use, and the design required depends upon the functions and conditions of use. If the relay must operate with a minimum of power and can operate at a moderate flux density, some of the nickel-iron alloys may be best to use for core and armature material. However, if higher flux densities can be employed to advantage, a low-silicon iron alloy known as "relay iron" is often used. The silicon tends to decrease aging and the tendency to "stick" after prolonged operation.

Loud-speaker magnets constitute another application of electromagnets. The voice coil of a loud-speaker operates in the air gap of an electromagnet energized by a constant d.c. Solid core materials are used in such electromagnets. In both relays and loud-speaker magnets, the aim of the designer is to keep as much of the total magnetic flux as possible in the air gap where the work is done and so design the magnetic structure that there will be a minimum of stray or leakage flux in other parts of the magnetic circuit. Since there is no insulator of magnetic flux, this involves proper shaping of the parts of the magnetic circuit and location of the magnetizing winding.

Another type of electromagnet that is coming into use is the recording, playback, and erasing heads used in magnetic recording. The magnetic core of such a head is usually constructed of one of the high-permeability nickel-iron alloys. The most common forms utilize the fringing flux across the very short air gap (of the order of 0.001 in.) for recording and erasing. A high value of initial permeability is particularly important for playback heads.

2. The core material for power transformers[2] is usually one of the various grades of silicon steel, the particular grade selected depending on the type of service, whether continuous or intermittent. If a minimum of distortion is required as in interstage coupling transformers, it is necessary either to make the core of relatively large cross section if silicon steel is used or to employ one of the high-permeability nickel-iron alloys. Considerations of space and cost usually govern the choice.

The inductance of coils having magnetic cores is not constant but depends upon the current. The variation is minimized either by an air gap in the magnetic circuit or by the use of powdered materials. In either case the effective permeability of the core material is considerably reduced, but the inductance is still much greater than could be obtained with the same winding without the magnetic core.

[2] Massachusetts Institute of Technology, "Magnetic Circuits and Transformers," Wiley, 1943.

3. Permanent magnets[1] are used for a great variety of purposes, chiefly in indicating meters, loud-speakers, and polarized relays. The choice of material for a given purpose depends upon a number of factors such as space requirements, degree of stability required, and cost. In many applications where space and weight are not important, the older types of tungsten or chromium magnet steels are satisfactory and more economical in cost than the newer alloys. In applications where space requirements are important and cost is a secondary consideration, the newer alloys such as the Alnicos, Cunife, Cunico, or Vectolite are usually employed. Sometimes the more expensive alloys will have to be used because no other materials are capable of giving the required performance.

CHAPTER 4

CAPACITANCE

By E. L. Hall[1] and Philip J. Franklin[1]

1. Capacitance. Capacitance is one of the three electrical quantities present in all radio circuits. The radio engineer endeavors to concentrate capacitance in definite well-known forms at definite points in the circuits, but capacitance exists between conductors in the circuits at different potentials and between the various conductors and the ground. Such capacitances, usually small, are ordinarily of no importance in the case of l-f or a-f currents but may be of great consequence in r-f circuits.

A *capacitor* is an electrical device in which capacitance plays the main role. Although some inductance and some resistance are present, these quantities are often of minor importance and sometimes may be neglected.

A capacitor has three essential parts, two of which are usually metal plates separated or insulated by the third part, called the *dielectric*.

The amount of electricity that the capacitor will hold depends on the voltage applied to it. This may be expressed as $Q = C \times V$. The *capacitance* is the ratio of the quantity of electricity and the potential difference or voltage, or $C = Q/V$, where Q is given in coulombs, C in farads, and V in volts. The capacitance is dependent on the size and spacing of the plates and the kind of dielectric between them.

2. Units of Capacitance. The unit of capacitance is the *farad*. A capacitor has a capacitance of one farad when one coulomb of electricity can be added to it by an applied voltage of one volt. As this unit is too large for practical use, a smaller unit, the microfarad, abbreviated μf, or one-millionth of a farad, is used. Capacitors for radio circuits usually have capacitances between a few thousandths and a few millionths of a microfarad. Another unit, the micromicrofarad, is often used. It is abbreviated $\mu\mu$f. This unit is also called a *picofarad*.

Another unit of capacitance sometimes used is the *centimeter*. The centimeter is equal to 1.1124 $\mu\mu$f.

3. Electrical Energy of Charged Capacitor. Work is done in charging a capacitor because the dielectric opposes the setting up of the electric strain or displacement of the electric field in the dielectric. The energy of the charging source is stored up as electrostatic energy in the dielectric.

The work done in increasing the charge in a capacitor is

$$dW = V\,dQ = \frac{Q}{C}\,dQ \qquad \text{or} \qquad W = \frac{1}{C}\int Q\,dQ = \frac{Q^2}{2C} = \frac{CV^2}{2}$$

where W is expressed in joules, Q in coulombs, and V in volts. The work done in charging the capacitor is independent of the time taken to charge it.

4. Power Required to Charge Capacitor. The average power required to charge a capacitor is given by the equation

$$P = \frac{1}{2}\frac{CV^2}{t}$$

where P is expressed in watts, C in farads, V in volts, and t in seconds. If the capacitor is charged and discharged N times per second, the above equation becomes

$$P = \tfrac{1}{2}CV^2N$$

[1] Diamond Ordnance Fuze Laboratories.

If an alternating emf of frequency f is used in charging the capacitor, the equation may be written

$$P = CE_0^2f$$

where P = power, watts
C = capacitance, farads
E_0 = maximum value of voltage
f = frequency, cps

5. Dielectric Materials. The dielectric of a capacitor may be found in solid, liquid, or gaseous form or in combinations of these forms in a given capacitor.

The simplest form of capacitor consists of two conducting electrodes or plates separated by air. This represents a capacitor having a gaseous dielectric. If this imaginary capacitor has the air between the plates replaced by a nonconducting liquid, such as transformer oil, and if the distance between the plates is the same as in the first case, it will be found that the capacitance has increased several times because the oil has a higher value of *dielectric constant* than air, which is usually taken as 1.

If the space between the plates is occupied by a solid insulator, a capacitor would result, which would be practical as far as the possibility of constructing it is concerned. It would be found, in this case also, that the capacitance of the capacitor was several times larger than when air was the dielectric.

The mechanical construction of either air or liquid dielectric capacitors requires the use of a certain amount of solid dielectric for holding the two sets of plates.

There are a great many dielectric or insulating materials available from which the engineer may choose. It is often found that a material that is very good from the electrical standpoint is poor mechanically, or vice versa. Air is the gas generally used as a dielectric. Compressed air has been used in some high-voltage capacitors, and compressed nitrogen, carbon dioxide, and sulfur hexafluoride are also in use.

Several kinds of oil have been used in capacitors, such as castor oil, cottonseed oil, and transformer oil. Electrolytic capacitors are in wide use in radio equipment as filters and by-pass capacitors where a large capacitance in compact form is required and either a d.c. or pulsating d.c. is applied.

Among the solids used as the dielectric are mica, ceramic materials, and paper. Solid insulators used as mechanical supports include quartz, glass, Isolantite, porcelain, mica, amber, hard rubber, Victron, and Mycalex.

6. Dielectric Properties of Insulating Materials.[1] Such properties as surface and volume resistivity, dielectric strength or puncture voltage, dielectric constant, and absorption are often considered in d-c and commercial-frequency applications. Such data are of little value if the insulating material is to be used at radio frequencies. For the latter application r-f measurements of various properties of the material are essential. A material that may be a satisfactory insulator for low frequencies may be worthless as an insulator at radio frequencies.

One of the most important properties of an insulator for radio frequencies is its power loss. This includes several factors which are difficult to separate but together indicate its suitability for radio purposes. The general idea of the imperfection of a capacitor is brought out in several names such as "power loss," "power factor," and "phase difference," but they are not identical terms.

Dielectric constant is another important property of a material that has a definite bearing upon its use at radio frequencies.

Neither power loss nor dielectric constant alone can be used in selecting the best insulator for a particular application at radio frequencies.

7. Dielectric Constant. The *dielectric constant* K of an insulating material is the ratio of the capacitance C_x of a capacitor using the material as the dielectric to the capacitance C_a using air as the dielectric, or $K = C_x/C_a$. This property of the material is sometimes called *inductivity* or *specific inductive capacity*.

The dielectric constant of a material is not a constant in the true sense of the word,

[1] Von Hippel, A., "Dielectrics and Waves," Wiley, 1954; "Dielectric Materials and Applications," Wiley, 1954.

but varies with the frequency, moisture content, temperature, voltage applied, and manner of applying it. For this reason the term "relative permittivity" is preferred by many engineers.

Table 1 gives the dielectric constants of a large number of electrical insulating materials.

8. Power Loss, Phase Difference, Power Factor, and Loss Factor. Electrical insulating materials are not perfect in their insulating qualities, and a certain amount of power is absorbed in them when used in an a-c circuit. A measurement of the power loss is the best single property that gives an indication of the suitability of an insulating material for use in radio circuits. Power loss can be expressed by a number of quantities, the most commonly used being resistance, power factor, phase difference, and phase angle.

When a.c. flows in a capacitor, the voltage across the capacitor lags somewhat less than 90 deg behind the current as shown by the angle θ (Fig. 1), called the *phase angle*. The complement ψ of the phase angle is called the *phase difference*. The cosine of the phase angle is called the *power factor*. The power loss in the insulating material is

$$P = EI \cos \theta \qquad \text{or} \qquad P = EI \sin \psi$$

where E = voltage across the capacitor
I = current through the capacitor, amp
θ plus ψ = 90 deg, as shown in Fig. 1

From the above, $\sin \psi = \cos \theta$, or the sine of the phase difference is equal to the power factor.
Fig. 1. Phase in a capacitive circuit.
Fig. 2. Capacitance with dielectric losses.
Fig. 3. Vector relations in a capacitor with dielectric losses.

When considering a capacitor having dielectric losses, such as current leakage, brush discharge or corona, dielectric absorption or resistance in the plates, joints, contacts, and leads, it is customary to think of it as a perfect capacitor C with a resistance R in series as shown in Fig. 2.

The voltage vectors may be shown as in Fig. 3, where the resultant voltage E flowing in the circuit is obtained by completing the vector diagram. The angle ψ is quite small for materials suitable for r-f insulators. For small angles the angle $\psi = \tan \psi$. In Fig. 3,

$$\tan \psi = \frac{RI}{I/\omega C} = R\omega C = 2\pi fRC$$

If the resistance, capacitance, and frequency can be measured, the phase difference can be calculated from

$$\psi = 2\pi fRC$$

where ψ = phase difference, radians
f = frequency, cps
R = resistance, ohms
C = capacitance, farads

The following equation is sometimes convenient when wavelength in meters is given:

$$\psi = 0.1079 \frac{RC}{\lambda}$$

where ψ = phase difference, deg
R = resistance, ohms
C = capacitance, $\mu\mu$f
λ = wavelength, m

For small angles, phase difference in radians is equal to power factor (nearly).

Power factor in per cent is 1.745 times phase difference in degrees. *Power factor in* per cent is given by the following equation:

$$\cos\theta = 2\pi fRC \times 10^{-7}$$

where $\cos\theta$ = power factor, per cent
f = frequency, kc
R = resistance, ohms
C = capacitance, $\mu\mu$f

The leakage of electricity by conduction through the dielectric or along its surface contributes to the phase difference but is generally negligible at high frequencies. A capacitor having leakage may be represented by a perfect unit capacitor with a resistance in parallel as shown in Fig. 4. The current divides between the capacitance
Fig. 4. Equivalent of capacitor with leakage.
Fig. 5. Vectors in capacitor with leakage.

and the resistance, I_R through the resistance being in phase with the applied voltage E, and I_C through the capacitance leading E by 90 deg as shown in Fig. 5. The resultant current I leads E by (90 deg $- \psi$), where ψ is the phase difference. In Fig. 5,

$$\tan\psi = \frac{E/R}{\omega CE} = \frac{1}{\omega RC} \quad \text{or} \quad \tan\psi = \frac{1}{\omega RC}$$

Power factor is a term that involves all the power losses in a capacitor. If the total power loss in a capacitor is W watts, the voltage applied to it is V volts (rms), and the current flowing through it is I amp (rms), the power factor of the unit is W/VI. The relation between I (amp) and V (volts) for a unit of capacitance C (μf) operating at a frequency f is

$$I = \frac{2\pi fCV}{10^6} = \frac{\omega CV}{10^6}$$

The power factor in per cent may be written

$$\cos\theta = \frac{W \times 10^6}{2\pi fCV^2} = \frac{W \times 10^6}{\omega CV^2}$$

Referring again to Fig. 2, showing the perfect capacitor C and resistance R replacing the actual capacitor, the value of R can be calculated from the equation $W = I^2R$. The quantity R is known as the *equivalent resistance* of the capacitor at the given frequency.

The expression $W \times 10^6/\omega CV^2$ for power factor can be changed into the expression involving resistance, capacitance, and ω by substituting I^2R for W and then substituting $\omega CV/10^6$ for I, giving power factor equal to

$$RC\omega \times 10^{-6}$$

The power loss or rate at which heat is generated within a dielectric is proportional to the product of the dielectric constant and the power factor. This product is known as the "loss factor" of the dielectric. The power loss in watts per cubic inch may be calculated from the following:[1]

$$P = 2\pi f G^2 K \tau \times 0.2244 \times 10^{-12}$$

where P = power loss, watts per cu in.
f = frequency, cps
G = voltage gradient in dielectric, rms volts per in.
K = dielectric constant
τ = power factor of dielectric

9. Dielectric Properties. Table 1 gives dielectric constant and power factor at certain frequencies of a large number of electrical insulating materials, as obtained from the sources given at the end of the table. In some cases data from different sources do not agree, but differences in composition, method of making measurements, and condition of samples may account for such disagreements.

10. Dielectric Strength. The *dielectric strength* of an insulating material is the minimum value of electric field intensity required to rupture it. Dielectric strength is usually expressed in kilovolts per centimeter of dielectric thickness. The fall in insulation resistance with rise in temperature is a factor of great importance in connection with the breakdown of a dielectric under the applied voltage. Insulating materials are not strictly homogeneous. The current leakage through an insulating material may perhaps be concentrated in a few small paths through the material, and the energy loss due to the leakage, although small, may be large compared with the area through which it is flowing. The paths of the current flowing through the dielectric become heated with a resulting lowering of the resistance of the path and an increase in the current leakage. The heating of the dielectric may lead to rapid deterioration, particularly if moisture is present, and ultimate breakdown. The length of time of the application of the voltage has a definite bearing upon the breakdown voltage. Most dielectrics will withstand for a very brief period a much higher voltage than they can when the voltage is applied for a longer period.

These effects have dictated two tests for capacitors: a high flash-test voltage of very brief duration, and the application of a much lower voltage for a longer period.

The dielectric strength of a material is usually found to be lower for r-f voltages than for a-f or d-c voltages. The rupturing voltage at radio frequencies depends on the rapidity with which the voltage is raised and is not nearly so definite a phenomenon

[1] Hoch, E. T., Power Losses in Insulating Materials, *Bell System Tech. J.*, **1**, 110, November, 1922.

as l-f puncture voltage. Dielectric strength of solid insulators is difficult to measure because of the complexity of the experimental effects. As the r-f currents flow in the material, heating, corona, flashover, and possible deterioration, blistering, or charring may result with consequent changing of voltage and current as the time of application elapses.

If high r-f voltages are applied to an air capacitor, a corona discharge may be set up which appears as a visible glow around high-potential metal parts, points, and sharp edges and is usually distinctly audible. These corona effects represent a power loss. Hence the construction of air capacitors for high voltages requires the rounding of all edges and corners and the avoiding of sharp points which encourage the formation of corona and flashover.

11. Dielectric Absorption. When a capacitor is connected to a d-c source of emf, the instantaneous charge is followed by the flow of a small and steadily decreasing current into the capacitor. The additional charge is absorbed by the dielectric. Similarly the instantaneous discharge of a capacitor is followed by a continuously decreasing current. The capacitor does not become fully charged immediately, nor does it completely discharge immediately when its terminals are shorted, but several discharges may be secured when the capacitor possesses dielectric absorption. The maximum charge in a capacitor cyclically charged and discharged varies with the frequency of charge.

If a capacitor evidencing dielectric absorption is used at radio frequencies, a power loss occurs which appears as heat. The existence of power loss indicates a component of emf in phase with the current as though a resistance were in series with the capacitor as shown in Fig. 2. The effect of dielectric absorption can be measured along with other losses in the capacitor, although dielectric absorption represents the chief power loss in solid dielectrics.

12. Calculation of Capacitance. Formulas are available for use in calculating the capacitance for a large number of geometrical shapes of conducting surfaces such as spheres and cylinders, either separated or concentric, and flat surfaces of various shapes. The usual types of capacitor calculations are concerned with two or more flat conductors.

When two conducting plates are parallel, close together, and of large area, the capacitance is given by

$$C = 0.0885 \times \frac{KS}{t}$$

where C = capacitance, $\mu\mu$f
K = dielectric constant (which is 1 for air)
S = area of one plate, sq cm
t = distance between plates, cm

When more than two plates are used, the formula becomes

$$C = 0.0885 \times \frac{KS(N-1)}{t}$$

where N = number of plates

The actual capacitance of a parallel plate capacitor is slightly larger than the value as calculated from the above formula, because of the fringing of the electric lines of force beyond the space between the plates. A correction[1] can be made for this fringing by slightly increasing the dimensions of the plates. A narrow strip of width w can be added to the actual plate dimensions. In the case of circular plates $w = 0.4413t$, and for plates with straight edges $w = 0.110t$, where t is the distance between the plates in centimeters.

13. Combinations of Capacitors. Combinations of two or more capacitors in a circuit are often arranged in either series or parallel. Perfect capacitors connected in parallel give a total capacitance equal to the sum of the capacitances of the individual capacitors. Capacitors connected in series give a resulting capacitance which may

[1] Coursey, Philip R., "Electrical Condensers," Sir Isaac Pitman & Sons, Ltd., London.

be calculated from the following:

$$C = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \cdots}$$

This formula gives the following expression in the case of two capacitors in series:

$$C = \frac{C_1 \times C_2}{C_1 + C_2}$$

The various elements such as tubes, sockets, mountings, and wiring in radio apparatus contain many small capacitances by virtue of the difference of potential existing between the numerous conductors insulated from one another. These small capacitances are known as *stray* capacitances. Although they are unimportant in some kinds of work, in other types of work, such as in amplifier design, they must be taken into account. In the case of resistance-coupled amplifiers, for example, these capacitances reduce the amplification at the higher audio frequencies and make a flat characteristic with high over-all gain impossible.

The effect of stray capacitances is eliminated in the case of units used as capacitance standards by shielding the insulated plates and grounding the shield. In this manner a definite capacitance is always assured for a given scale setting.

14. Effect of Frequency on Capacitance. In the best capacitors the effect of frequency is nil in the lower radio range. A criterion of a suitable capacitor for use as a standard is that its capacitance shall be the same for two different sets of charging and discharging conditions. A variable air capacitor, such as the National Bureau of Standards type described on p. 120 of the Bureau's *Circ.* 74, gives the same capacitance at 100 and at 1,000 charges and discharges per second. A capacitor having considerable solid dielectric in its make-up will show a difference in capacitance with frequency. The quantity of electricity that flows into a capacitor during a finite charging period is greater than would flow in during an infinitely short charging period. Consequently the measured or apparent capacitance with a.c. of any finite frequency is greater than the capacitance on infinite frequency, the latter being called the *geometric* capacitance. The capacitance decreases as the frequency increases.

FIG. 6. Resonant frequency vs. capacitance for tab paper, metallized, mica, and ceramic capacitors. Deviations from the curve of all types are about the same. (*From Geiser.*)

The length of the internal leads should be kept as short and direct as possible to minimize the inductance of the leads that acts to give an apparent change of capacitance with frequency. The amount of this change can be calculated from $C_a = C(1 + \omega^2 CL \times 10^{-12})$, where C_a is the apparent or measured capacitance, C is in microfarads, and L is in microhenrys.

Resonance is defined as the frequency at which the capacitance and series inductance of a capacitor produce zero reactance. It follows that the resonant frequency can be raised by minimizing lead inductance.

The more nearly opposite the lead connections, the lower the effective series inductance becomes. This is demonstrated by an increase in the two-terminal resonant frequency.

The resonant frequency increases with decreasing capacitance value. A plot of capacitance vs. frequency on loglog paper, shown in Fig. 6, yields a straight line for similar capacitors.

Very little difference is noted[1] in resonant frequency between inserted tab paper, mica, metallized, and ceramic capacitors.

15. Capacitor Types. There are many ways in which capacitors might be classified: by their construction, size, voltage rating, use, dielectric, or fixed or variable capacitance. The capacitors used in various radio applications are found in innumerable sizes, shapes, and uses. *The two simplest divisions into which they may be classified have to do with their capacitance, i.e., whether it is fixed or variable.*

16. Types of Fixed Capacitors. Fixed capacitors are available in all ranges from a few micromicrofarads to several microfarads, for any voltage rating, and in innumerable shapes and dimensions, all depending on the use for which the unit is intended.

The three general methods used in construction of fixed capacitors are: (1) winding, which is used for flexible dielectrics such as impregnated paper, plastic films, and some glasses; (2) stacking, which is used for stiff, brittle dielectrics such as mica, glass, and some combinations of organic and inorganic materials; and (3) molding or stamping, which are used primarily with ceramics which are molded wet into a circular or rectangular plate or tube and then fired.

Wound capacitors are formed by winding two metal-foil electrodes or ribbons in conjunction with one or more dielectric ribbons. The number of layers of dielectric is determined by the desired voltage rating. There are two types of windings, *inserted-tab* and *extended-foil*. In winding the inserted-tab type, the foil used is narrower than the dielectric and contact is made with the foils by inserting one or more tabs per foil during the winding. In the extended-foil type the foils have the same width as the dielectric. The foils are staggered so that they extend over the edges of the dielectric. The terminals are soldered to the extending foil at the opposite ends. The latter type of construction produces capacitors having minimum series resistance. A third type of wound capacitor, employing metalized dielectric, is in common use. In this type a thin aluminum or zinc film from 25 to 100 $m\mu$ in thickness is deposited on the dielectric. This construction increases the series resistance, but for many applications the physical sizes are only about one-third of those of the more conventional designs.

The stack-type capacitor is normally built up by alternating sheets of metal foil and dielectric. The sets of foils of opposite polarity are brought out at opposite ends and soldered together. The whole stack of plates is rigidly clamped in such a way as to grip the plates firmly in the center and expel all air from the stack. A casing of some moisture-resisting insulation, usually phenolic or ceramic, is then molded around the unit.

17. High-voltage Capacitors. It is customary to mount large high-voltage capacitors in steel tanks which are filled with a high-flash-point oil which protects against dirt and moisture, prevents flashover along the capacitor sections, insulates the capacitor from the tank, and conducts heat away from the capacitor elements.

Fixed high-voltage vacuum- or gas-filled capacitors are available for transmitters or power amplifiers. They are normally two cylindrical metal elements mounted in an exhausted glass tube. The gas-filled capacitors usually employ sulfur hexafluoride, argon, or helium. See also Sec. 27.

Fixed vacuum-dielectric capacitors of about 5 to 50 $\mu\mu f$ are used as all or part of plate tank, high-voltage coupling, by-pass, and neutralizing capacitance at high frequency.

18. Ceramic Capacitors. Development of ceramics having high and controllable dielectric constants has been in progress for a number of years and capacitors utilizing the properties of these ceramics are in very wide production and use. Barium-strontium titanates have been found to possess dielectric constants from 10,000 to 18,000. Barium-calcium titanates have lower dielectric constants, and barium-magnesium titanates still lower values. The body is prepared as a wet mix which is subsequently molded or stamped to the desired shape and processed at high tempera-

[1] Geiser, D. T., "An Investigation of Lowest Resonance Frequency in Commercially-available By-pass Capacitors," Convention Record of the IRE, 1954 National Convention, Part 3, p. 43.

tures such as 1250 to 1400°C. Capacitors formed of tiny disks of these materials have been used in the construction of "matchbox" receivers and "lipstick" transmitters in which all components are very small.

The ceramic and silver-mica capacitors have plated-on or fired-on silver electrodes to which the leads are soldered. These are normally protected by either phenolic, epoxy, or ceramic cases.
FIG. 7. Capacitance-temperature characteristics of several capacitors.
FIG. 8. Dependence of capacitance on temperature for several capacitors

The change of capacitance of a capacitor with temperature is dependent on the dielectric and impregnant used. Figures 7 and 8 show the per cent change in the capacitance with temperature of several capacitors using different dielectrics. In most applications predictable temperature coefficients are not required, provided the total change in capacitance is less than some desired limit. It is for this reason that some capacitors are marketed as GMV (guaranteed minimum value). In some applications, however, such as for tuning capacitors, it is important that the capaci-

tance remain fixed with changes in temperature or change predictably within narrow limits so that they may be used to compensate for warm-up drift in inductors. Ceramic tube or disk capacitors are available for this purpose and are manufactured with predictable positive, zero, or negative temperature coefficients from +100 to −5,600 ppm per °C in a capacitance range from 0.3 to 4,500 μμf.

Where high stability with respect to temperature is required, silver-mica capacitors have proved to be very useful. They suffer somewhat from the tendency for the silver coating to migrate in the presence of moisture and with d-c voltages impressed across the terminals.

19. Type Designations.[1] RETMA standards and MIL specifications make use of type designations to describe capacitors and their properties fully in the form of a code containing numerals and letters. An example is given below:
Component Designation. Fixed mica capacitors are identified by the symbol CM. Fixed paper capacitors are identified by the symbol CP, etc. In RETMA standards the two-letter symbol is preceded by the letter R to indicate RETMA standards are being used.

Table 2. 1957 RETMA Standard Color Coding for Molded Mica Capacitors

White for mica

Designation	Q	Insulation resistance not less than	T.C. not more than	Capacitance drift not more than	Color	Tolerance	First and second significant figure of capacitance	Decimal multiplier of capacitance
Class A	a	3,000 megohms	± 1,000 ppm/°C	± (5% + 1 μμf)	Black	20%(M)	0	1
Class B	b	6,000 megohms	+ 500 ppm/°C	+ (3% + 1 μμf)	Brown	1%(F)	1	10
Class C	b	6,000 megohms	± 200 ppm/°C	± (0.5% + 0.5 μμf)	Red	2%(G)	2	100
Class D	b	6,000 megohms	± 100 ppm/°C	± (0.3% + 0.1 μμf)	Orange	3%(H)	3	1,000

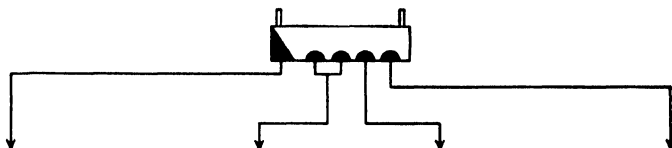
					Silver	10%(K)	...	0.01

a. Q must be greater than 30% of a minimum allowable Q for other characteristics.
b. Minimum acceptable Q between 0.5 and 1.5 Mc is defined by a curve; value varies with capacitance.

Case Designation. The case designation is a two-digit symbol that identifies a particular case size and shape.

Characteristic. The characteristic is indicated by a single letter which is the class of electrical properties into which the unit falls. Reference is made to Table 2 for details.


[1] A considerable amount of information on the numerous types of capacitors now available for commercial and military use will be found in "Electronic Components Handbook," McGraw-Hill, 1957.

Capacitance Value. The nominal capacitance value in micromicrofarads is indicated by a three-digit number. The first two digits are the first two digits of the capacitance value in micromicrofarads. The final digit signifies the number of zeros that follow the first two digits. If more than two significant figures are required, additional digits may be used, the last digit always indicating the number of zeros.

Capacitance Tolerance. The symmetrical capacitance tolerance in per cent is designated by a letter as shown in Table 2.

Color Coding. On most capacitors there is sufficient space available on the body of the unit for all appropriate information to be printed on it. On the small capacitors, however, like mica and ceramic units, a color-coding scheme has been adopted for marking the

Table 3. 1957 RETMA Standard Five-dot Color Coding for Ceramic Dielectric Capacitors

Temperature coefficient of capacitance	Color	First and second significant figure of capacitance	Decimal multiplier of capacitance	Tolerances of capacitance	
				Nominal $\leqq$ 10 μμf	Nominal > 10 μμf
0 ppm/°C	Black	0	1	±2.0 μμf	±20%
−33 ppm/°C	Brown	1	10	±0.1 μμf	± 1%
−75 ppm/°C	Red	2	100	. . . .	± 2%
−150 ppm/°C	Orange	3	1,000	. . . .	± 3%
−220 ppm/°C	Yellow	4	10,000

−750 ppm/°C	Violet	7			
a	Gray	8	0.01	±0.25 μμf	
b	White	9	0.1	±1.0 μμf	±10%

a. This is a general-purpose capacitor having any nominal temperature coefficient between +150 and −1,500 ppm/°C.

b. This is a general-purpose capacitor having any nominal temperature coefficient between 100 and −750 ppm/°C.

required information on each unit. Table 2 gives the 1957 RETMA standard color coding for mica capacitors and Table 3 gives the same information for ceramic capacitors. In the case of tubular ceramic capacitors an alternate coding using bands of colors (Fig. 9) rather than dots is extensively employed. The only requirement is that the first band be distinguishable from the last band. This is usually accomplished by making the first band wider.
Fig. 9. Capacitor color-code arrangement.

20. Electrolytic Capacitors. Another type of fixed capacitor with important applications is known as the electrolytic capacitor. Its advantages are low cost and high capacitance as compared with other types of fixed capacitors.

The electrolytic capacitor consists of three essential components: the anode, the dielectric film, and the electrolyte. The anode is made of either aluminum or tantalum of high purity and forms one plate of the capacitor. The dielectric film is

formed electrochemically on the anode and is very thin. The electrolyte may be either a liquid, paste, or more recently a solid substance. It is the second plate of *the capacitor, insulated from the anode plate by virtue of the dielectric film formed* on the latter.

According to the electrolyte employed, electrolytic capacitors may be divided into three general classes: (1) dry electrolytic capacitors in which a pastelike form of electrolyte is used, (2) wet electrolytic capacitors in which a liquid or waterlike electrolyte is used, and (3) solid electrolytic capacitors in which a solid electrolyte is used. With the recent development of the solid electrolytic capacitor the designation dry electrolytic capacitor for those units employing paste electrolyte seems improper, but for the purpose of this book this term will be retained.
FIG. 10. Electrolytic-capacitor construction.

The electrolyte in the case of dry electrolytic capacitors is absorbed in porous paper and held in position adjacent to the anode foil by this paper. In addition another metal foil, generally though perhaps erroneously called the cathode foil, is incorporated for the purpose of making electrical contact to the electrolyte-saturated paper.

In the wet type the electrolyte is a dilute aqueous solution. The anode member with adhering dielectric film is suspended in a can. For aluminum electrolytic capacitors the can is generally aluminum; for tantalum electrolytic capacitors the can is a silver-plated metal such as copper or brass. The can is filled with the electrolyte and acts as the electrical connection to the electrolyte similar to the cathode foil in the case of the dry electrolytic capacitor.

All aluminum electrolytic capacitors have anodes of aluminum foil. Tantalum capacitors may employ tantalum foil, slugs of sintered porous tantalum, or tantalum wire as anode material.

The solid electrolytic capacitor contains no electrolyte. The most commonly used structure consists of the conventional porous tantalum anode, a layer of semiconducting material such as manganese dioxide, a suitable conductor, and a metallic terminal. Recently, solid electrolytic capacitors that use a tantalum wire anode have become available. Foil-type solid electrolytic capacitors, as well as units employing aluminum foil, are under development. In general, the use of solid electrolytic capacitors is increasing.

FIG. 11. Electrolytic-capacitor characteristic.

For a given area of anode surface the capacitance in microfarads is inversely proportional to the thickness of the dielectric film. The film thickness is proportional to the voltage during electroformation of the film. Therefore, units with very low voltage ratings may be made with very high capacitances. If the anode area is such as to give 8 μf when the working voltage is 500 volts d-c, then the same area at lower working voltages will yield a capacitance as indicated on the curve of Fig. 11. The ordinary ranges are 500 to 6,000 μf in capacitance for voltage ratings of 6 to 60 volts d-c and 2 to 100 μf with voltage ratings of 100 to 150 volts d-c.
21. Electrolytic Capacitor Characteristics. The d-c voltage which an electrolytic capacitor can withstand is governed by the voltage at which the original film is applied. For the more common polar-type capacitors it is necessary that the anode always be connected to the positive side of the voltage source. The capacitor connected in this manner will operate satisfactorily as long as the applied voltage is of correct polarity and does not exceed rated voltage for more than a few seconds at a time. A reversal of potential will cause the unit to draw considerable current even at low voltages. A d-c voltage in excess of rated causes the unit to draw appreciable

leakage current. A nonpolar-type electrolytic capacitor is composed of two units mounted back to back in the same case. The capacitor will operate satisfactorily no matter what the polarity if the voltage rating is not exceeded.

Dry electrolytic capacitors have a definite breakdown voltage at which permanent failure occurs. Momentary surges less than breakdown voltage but higher than operating voltage will ordinarily do no damage.

Electrolytic capacitors have a power factor that is considerably higher than other types of fixed capacitors. This is due in part to the fact that one of the conducting plates is the electrolyte, which has considerably higher resistance than the conventional metallic plates of the other types. In effect this places a resistance in series with the capacitor and hence causes a high power factor of the entire unit. Dry electrolytic capacitors have a power factor of about 6 per cent at 60 to 120 cps. Power factors increase with frequency and for this reason electrolytic capacitors are generally confined to l-f applications. Tantalum electrolytic capacitors are superior to aluminum electrolytic capacitors in power factor because the dielectric film in the tantalum units is chemically resistant to a wider range of electrolytes than the film in the aluminum units and lower electrical resistance electrolytes can be employed.

22. Etched-foil Types. Methods of treating the smooth foil surface in such a way as to make it extremely rough have been applied to electrolytic capacitors. The anode then has an increased total area over and above the original smooth surface. The dielectric film follows the contours of the foil, and the result is a great increase in capacitance with no increase in volume for any given working voltage.

Several methods have been evolved for formation of a roughened surface for the anode foil. Chief among these are as follows: (1) etching, whereby the smooth surface is attacked either chemically or electrochemically, and (2) spraying, whereby the metal is sprayed in a molten state on a suitable carrier medium.

23. Effect of Temperature on Characteristics. Electrolytic capacitors operate best under normal conditions of temperature. The limitations of the electrolyte and the film are the governing factors in the operation of this type of capacitor.

Extremely high temperatures cause the electrolyte to dry out and increase in resistivity with consequent increase in power factor when normal temperature is again reached. Furthermore the increase in d-c leakage current with temperature must be considered since there is danger of the start of a destructive cycle due to the generation of internal heat because of the increased d-c leakage.

Low temperature causes a decrease in capacitance and an increase in power factor. This is more pronounced in aluminum than in tantalum capacitors using liquid electrolyte and much more pronounced in both of these than in solid tantalum capacitors. These changes are temporary and are restored to normal when normal operating temperatures are again reached.

When high operating temperatures are to be experienced, the units should be hermetically sealed in metal cans. This construction limits the loss of electrolyte to a minimum, and longer life can be expected.

24. Comparison of Aluminum and Tantalum Electrolytic Capacitors. Tantalum capacitors are superior to aluminum capacitors in most respects. The exceptions are that at present tantalum electrolytic capacitors cannot be formed at so high a forming voltage or operated at so high a working voltage as aluminum capacitors. Single-cell tantalum capacitors employing liquid electrolytes are rarely found rated at higher than 150 volts d-c and the solid tantalum units are yet to be fabricated for ratings above 35 volts d-c. Among the three types of tantalum capacitors containing a liquid electrolyte, the type employing an anode of sintered porous tantalum will operate over the widest temperature range (−55 to 200°C) but this type has the least convenient shape.

The use of etched tantalum foil as anode material allows construction of capacitors having a smaller diameter and greater mechanical stability than porous-plug-type units, but foil-type capacitors cannot be operated at temperatures above 125°C. The use of a wire-type anode allows further savings in space, but the capacitance and voltage ratings of these capacitors are lower at the present time, and their maximum

usable temperature now is 85°C. The solid-electrolyte units available to date cannot be used above 85°C, but their low-temperature characteristics are superior to any electrolytic capacitors containing a liquid electrolyte. Because of the lesser increase in power factor at low temperature, solid-electrolyte capacitors can be used satisfactorily at −80°C, while no liquid-electrolyte unit has been rated for less than
FIG. 12. Temperature characteristics, plain and etched foil.

−55°C. The electrical characteristics of solid-electrolyte capacitors are also less frequency-dependent, so that tests on these units have been extended up to 10 Mc, compared with a maximum of 100 kc for the liquid-electrolyte types. In addition, the storage ability of solid-electrolyte capacitors is greatly superior to that of the other types.

Table 4 lists voltage rating, capacitance, and temperature ratings as well as the dimensions of some characteristic units of each of the described types of electrolytic capacitors. The cost of tantalum electrolytic capacitors is several times that of the aluminum electrolytic capacitors. It is worth noting that tantalum electrolytic capacitors are finding their main application in miniature and subminiature circuits where their high capacity-to-volume ratio and long life meet requirements very nicely.

Table 4. Comparative Size and Performance Data for Five Types of Electrolytic Capacitors*

Type	Voltage rating, volts	Capacitance, μf	Operable temp range, °C	Physical size	
				Length, in.	Diam, in.
Dry Al	450	80	−40 to 85	4.250	1.375
	600	10	−20 to 85	2.938	1.063
	450	10	−40 to 85	1.688	0.875
Porous Ta slug	90	50	−55 to 85	0.688	0.875
	60	50	−55 to 200	0.688	0.750
	90	10	−55 to 85	0.688	0.468
	70	10	−55 to 125	0.688	0.468

25. Applications. The nature of electrolytic capacitors makes them particularly suitable for filter circuits in power supplies where a relatively high capacitance is required together with the ability to withstand a d-c potential and small superposed a-c ripple. Second only in importance is the use as a-f by-pass capacitors across screen grids and cathode bias resistors. The use of a-c electrolytics wherein the cathode foil is replaced with a second anode is important in capacitor motor service. These latter units are divided into two classes: those for intermittent duty and those for continuous duty. The former are rated at from 30 to 500 μf at 100 volts a.c. and the latter at 10 to 50 μf at 25 volts a.c.

The intermittent-duty type functions only during the starting of a capacitor motor (capacitor start-induction run). The continuous-duty type functions in the smaller motors rated at about 1/100 hp and is continuously on voltage during the operation of the motor.

26. Testing. The circuit of Fig. 13 is generally used to test electrolytics in production. E_{dc} supplies a polarizing voltage so that the voltage across the capacitor will be pulsating d.c. The isolating capacitor prevents short-circuiting the polarizing voltage. If E_{dc} is maintained at a constant value, the a-c milliammeter may be calibrated in terms of the capacitance under test. I_{dc} reads the d-c leakage current.
FIG. 13. Production testing circuit for electrolytic capacitors.

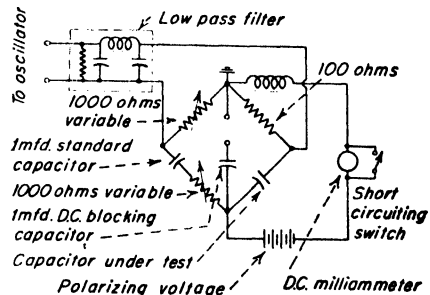
For the accurate measurement of capacitance and power factor, bridge systems such as those shown in Fig. 14 or 15 should be used. They are essentially standard bridge systems rearranged to permit the application of a polarizing voltage.
FIG. 14. Capacitor measuring circuit.


FIG. 15. Capacitance and power-factor measurement.

27. Variable Capacitors. The most common type of variable capacitor consists of a series of parallel metal plates fastened to a shaft capable of rotation so that the moving plates intermesh with a set of fixed plates. Air is the main dielectric in such capacitors, although some solid insulating material is required to ensure that the two sets of plates are correctly located with respect to each other. Many ways of insulating the plates from each other have been devised, using one or more pieces of the insulating material in sheet, rod, or bar form. Phenolic, hard rubber, pyrex, porcelain, fused quartz, and steatite are some of the materials used for such insulators.

The most common use of a variable capacitor is in association with a coil, the combination forming a circuit resonant to a band of radio frequencies depending upon the coil constants and the capacitance range of the capacitor. For a number of applications it is more convenient to have the capacitance change in a different way than proportional to the angle of rotation of the plates. This first resulted in the "decremeter" plate and the straight-line wavelength plate. As the use of frequency rather than wavelength became common, the straight-line frequency plate came into use and later the "mid-line" plate. There are other possibilities such as straight-line percentage wavelength and straight-line percentage frequency, the latter being of advantage in frequency measurements. In any of the above shapes or classifications, the movable plates formerly were so shaped as to give the desired frequency or wavelength curve. This resulted in an ill-shaped plate difficult to balance or to hold to a desired setting. In some cases semicircular rotating plates were used with the fixed plates cut away so as to obtain the desired curve. In any of the special forms of plates the plate shape may vary. The minimum and maximum capacitances of the circuit play a large part in determining the outline of the plate.

Brass or aluminum plates and steel shafts are ordinarily used. If the capacitor is intended for use on high voltages, the spacing between opposite plates must be sufficient to avoid a flashover or arcing between plates. It is customary to round off all sharp edges and corners in such capacitors to avoid flashover.
FIG. 16. Flashover voltage at 60 cycles of 2,000-kva capacitor.

Capacitors of the air type are often filled with oil, which increases the voltage that they can stand and increases the capacitance from two to five times depending on the dielectric constant of the oil used.

Compressed-air capacitors were formerly used in some radio transmitting stations. The voltage that such a capacitor will stand is increased without changing the capacitance.

Compressed-gas capacitors, utilizing nitrogen under pressure up to 2,000 psi as the dielectric, are now being extensively used in broadcast transmitters. The advantages of low loss and permanent characteristics have long been recognized, but it is only of recent date that any attempt has been made to offer a wide commercial selection of this type of capacitor.

One manufacturer offers three lines with flashover ratings of 15, 20, and 30 kv rms at 1,000 kc, and capacitance ranges up to 1,000, 1,500, and 2,000 $\mu\mu$f, respectively. These are available in fixed, adjustable, or continuously variable types. Special units have been built with flashovers up to 60 kv rms and capacitances up to 20,000 $\mu\mu$f.

Construction varies somewhat with different manufacturers. One offers a completely nonmagnetic assembly using heat-treated aluminum tank and end closures. As a typical example, a variable capacitor having 30 kv rms flashover rating will have a height of 36 in., an over-all diameter of 12 in., and a weight of 90 lb.

Gases other than nitrogen have been used, some of which show considerable promise in increasing flashover voltage and reducing size and weight. These are available in either fixed or variable capacitance types and in sizes from 100 to 2,000 $\mu\mu$f.

Variable high-voltage vacuum capacitors are among the recent developments. These capacitors are similar to the fixed high-voltage vacuum units but have mechanical arrangements to vary the capacitance a few micromicrofarads in the vicinity of 10 or 20 $\mu\mu$f. A larger unit covers a range from 250 to 350 $\mu\mu$f at 10,000 volts peak. Variable vacuum capacitors in which capacitance varies linearly, with respect to shaft rotation, from 10 to 60 $\mu\mu$f are used as plate tank capacitors in high-frequency applications.

28. Gang Capacitors. The single-dial control radio receiver brought problems to the designer in how to tune two to five circuits accurately using a corresponding number of similar coils and variable capacitors operating on the same shaft. As it is practically impossible conveniently to manufacture two capacitors exactly alike, to say nothing of three or four alike, so that their capacitances shall be exactly the same throughout the complete rotation of the capacitor plates and accurately tune the capacitors with the same number of similar coils which differ slightly in value, it has been customary to balance or equalize these tuned circuits by the addition of small paralleling capacitors called *trimmer* or *padder* capacitors. Such capacitors can be obtained matched to one-half of 1 per cent. It is possible to obtain two to four capacitors called *gang* capacitors for radio receivers arranged with their shafts in line and operated by one dial, matched to one-half of 1 per cent. The individual capacitors may be separated from one another by metal shields if desired.

Earlier forms of trimmer capacitors used a combination of mica and air as the dielectric. Adjustment in capacitance was accomplished by turning a screw which moved one of the plates nearer the other. A recent design incorporates several concentric cylinders supported on a ceramic member and arranged to interweave so as to change the capacitance from 2.5 to 30 $\mu\mu$f. Another trimmer of recent design employs a metalized glass tube with a metal core within, which may be moved with respect to the metalized coating. Several sizes are available with d-c breakdown voltages from 1,500 to 2,000 volts.

A still more recent design employs optically flat base and ceramic rotor. Fired silver electrodes on base or rotor top permit changing capacitance by varying the overlap, but the change per degree of rotation is nearly constant. The temperature coefficient may be controlled within narrow limits.

Fig. 17. Dimensions useful in determining capacitance.

29. Design Equations for Variable Air Capacitors. The capacitance of a capacitor made up of three plates as indicated in Fig. 17 can be obtained by determining the area of the overlapping plates, the distance between the adjacent plates, and substitution of these values in the general equation given in Sec. 12. The area of the shaded portion of Fig. 17 is $\frac{1}{2}\pi(r_1^2 - r_2^2)$. The distance between the plates is $\frac{1}{2}(s - t)$. Substituting these values in the general equation, the capacitance is given by

$$C = \frac{0.0885 \times \frac{1}{2}\pi(r_1^2 - r_2^2) \times (3 - 1)}{\frac{1}{2}(s - t)}$$

The maximum capacitance of a unit with N plates can be obtained by using a similar equation which may be written

$$C = \frac{0.278(r_1^2 - r_2^2)(N - 1)}{(s - t)}$$

In the above equation C is in micromicrofarads and the dimensions r_1, r_2, s, and t in centimeters. These equations neglect the capacitance through the solid insulation which is used in the capacitor and the fringing effect, the correction for which is in

$a_2 = \dfrac{\sqrt{\text{max. cap.}} - \sqrt{\text{resid. cap.}}}{180}$	$a_3 = \dfrac{1}{180}\left\{\dfrac{1}{\sqrt{\text{resid. cap.}}} - b_3\right\}$	$a_4 = \text{resid. cap.}$
$b_2 = \sqrt{\text{resid. cap.}}$	$b_3 = \dfrac{1}{\sqrt{\text{max. cap.}}}$	$b_4 = \dfrac{\text{log. (max. cap)} - \text{log (resid. cap.)}}{78.174}$

Common constants $k = \dfrac{\text{total plate area} - 180\,K}{\text{max. cap.} - \text{resid. cap.}}$

$$K = \frac{r^2}{114.6}$$

Sec. 12. Many capacitors are made to have as small a minimum capacitance as possible, giving a large ratio of maximum to minimum capacitance, but this is of doubtful advantage, as slight changes of capacitance due to warping of plates or wear in bearings will cause a relatively large error at the lower end of the scale but practically no noticeable effect at the maximum capacitance end of the scale.

A semicircular plate capacitor gives a capacitance calibration curve similar to C shown in Fig. 18. With the exception of the portions near the ends of the curve, it is practically a straight line. In practice, the lower 10 and upper 5 or 10 deg of a 180-deg scale are not used, so as to avoid the curvature in the calibration curve in these regions. Zero setting does not give zero capacitance.

A curve for such a capacitor used with a coil is shown by F in Fig. 18. The frequency changes very rapidly on the lower part of the scale. A slight capacitance change would make a large frequency change. Therefore, when using frequency meters having semicircular plate capacitors that constitute the main capacitance of the circuit, the coils should be so designed as to give overlaps without resort to the low-capacitance end of the scale.

Fig. 18. Characteristics of semicircular plate capacitor.

As the wavelength λ of a wavemeter circuit is proportional to $\sqrt{LC}$, if L is assumed to be constant, $\lambda \propto \sqrt{C}$ and $\sqrt{C}$ is proportional to the square root of the setting θ. For a uniform wavelength condenser it is necessary to have C vary as the square of the setting θ, or $C \propto \theta^2$.

θ, deg	Radius, cm		
	R_2	R_3	R_4
0	2.49	8.25	1.93
5	2.56

160	....	1.76	5.04
170	....	....	5.40
180	4.38	1.65	5.80

Again, it may be desirable that the percentage change in capacitance for a given angle of rotation of the plates be the same for all parts of the scale as in the Kolster decremeter.[1] The polar equation for the boundary curve is

$$r = \sqrt{2C_0 a\epsilon^{a\theta} + r_2^2}$$

[1] *Nat. Bur. Standards Circ.*, **74**, p. 117. *Nat. Bur. Standards Sci. Paper* 235.

where C_0 = capacitance when angle $\theta = 0$

a = constant = percentage change of capacitance per scale division

ϵ = 2.71828

r_2 = radius of cutout portion to clear washers separating variable plates

The equations and tables on page 4-20 have been compiled by Griffiths.[1] The three types of plates given are for equivalent capacitors having a capacitance at zero setting *of 36 μμf, with a plate area of 20 sq cm.*

The paper mentioned above gives the data for the radii at different angles for the capacitors mentioned in the table of equations on page 4-21.

30. Effect of Putting Odd-shaped Plate Capacitors in Series or Parallel. If any of the above capacitors are placed in parallel or in series with another capacitor, the straight-line calibration will be altered. If paralleling capacitors are used, the plate shape would require recalculation, after which the plate would become more nearly semicircular. If a capacitor is added in series, the calculation of the plate shape is more difficult. Griffiths[2] gives complete equations for a number of series combinations, the following table applying to the cases indicated where maximum capacitance of variable capacitor = 500 μμf, minimum capacitance of variable capacitor = 36 μμf, series fixed capacitance = 500 μμf, total plate area = 20 sq cm, r = radius of inactive semicircular area of moving plate = 1.2 cm.

R_6, corrected square law of capacitance with series fixed capacitance.
R_7, inverse square law of capacitance with series fixed capacitance.
R_8, exponential law of capacitance with series fixed capacitance.

31. Important Considerations in Design. It is not difficult to find a large number of capacitors on the market that will answer the needs of any application in radio receivers. The manufacture of capacitors for such use has been brought to a high state of development, both electrically and mechanically. The design problems here are simpler in that low power and low voltage are to be handled.

[1] Griffiths, W. H. F., Notes on the Laws of Variable Air Condensers, *Exptl. Wireless and Wireless Engr.*, **3**, 3, January, 1926.

[2] Griffiths, W. H. F., Further Notes on the Laws of Variable Air Condensers, *Exptl. Wireless and Wireless Engr.*, **3**, 743, December, 1926.

When capacitors for radio transmitters are designed, provision must be made for handling high power and high voltage. The use of very high radio frequencies has added to the problem by requiring better insulating materials. Insulators that were satisfactory at low radio frequencies have been found to heat up and be unsuited for frequencies such as 30 to 100 Mc and higher.

The following classification shows how capacitors for transmitting sets could be divided with respect to the voltages to which they are subjected:

Those subjected to steady d-c voltages only.
Those subjected to l-f voltages only.
Those subjected to damped r-f voltages only (obsolete).
Those subjected to steady c-w r-f voltages only.
Those subjected to modulated c-w r-f voltages only.
Those subjected to d-c voltages with superimposed r-f voltage.
Those subjected to l-f voltage and superimposed r-f voltage.

The last four of the above divisions could be further subdivided into those for use on frequencies up to about 3,000 kc, those for use on frequencies from 3,000 to about 25 Mc, and those for use on frequencies of 30 Mc and above. The two latter classes require special construction.

In specifying the rating of capacitors for use in radio transmitters, the following data should be given: capacitance, current, frequency, nature of voltage to be applied. A knowledge of the maximum r-f voltage and maximum current permissible is important. A capacitor should never be operated at more than half the breakdown voltage. In the case of r-f voltages this fraction should be much smaller.

32. Standards of Capacitance. Fixed capacitors using the best grade of mica or fixed air condensers may be used as capacitance standards for audio frequencies. A variable air capacitor is essential as a standard in many radio measurements.

High-grade mica capacitors can be employed as standards after calibration as to capacitance and power factor over the range of frequencies at which they are to be used.

An important requirement of a standard capacitor is that the capacitance remain constant, the prerequisite of which is rigidity of construction, which is more difficult to secure in a variable than in a fixed capacitor. There should be no relative motion possible between the movable plates and the pointer. There should be no stops against which the pointer or movable plates may strike and thus destroy the calibration. The manner of insulating the two sets of plates is of great importance, not only in fulfilling the rigidity requirement, but in minimizing the power loss. An insulating material having a low temperature coefficient of expansion should be used, so that the capacitance will not change perceptibly with temperature. As small an amount of solid insulating material as possible should be employed, keeping it well out of the electric field. This field is quite intense near the high-potential post. All insulation should be avoided in the vicinity of that terminal if power factor is to be kept low.

The capacitor should be provided with a metal shield, which may be grounded during measurements if the capacitance is to remain constant. The leads inside the capacitor should be as short and direct as possible. The resistance of leads, plates, and contacts should be kept to the minimum. Flexible connection to the moving plates should not be used in a capacitor used as a standard.

Although it has been customary and is permissible in some measurements to neglect the small resistance and inductance found in variable air capacitors made for precision laboratory work, yet, as the frequency is increased to 5 Mc and higher, such omissions may result in considerable inaccuracy in the results. These small residual impedances, when taken into account, give an equivalent circuit for the variable air capacitor[1] as shown in Fig. 19, where C is the static capacitance of the capacitor, R the resistance loss in the metal parts, L the inductance of the leads and connections of stacks of plates, and G the conductance or losses in the solid dielectric parts.

[1] Field, R. F., and D. B. Sinclair, A Method for Determining the Residual Inductance and Resistance of a Variable Air Condenser at Radio Frequencies, *Proc. IRE*, **24**, 255, February, 1936.

The resistance R is practically independent of capacitance setting and increases with frequency because of skin effect, being proportional to the square root of the frequency at higher frequencies.

The effect of the inductance L is to cause the apparent capacitance to be greater than the actual capacitance, as may be seen from the following equation:

$$C_a = \frac{C}{1 - \omega^2 LC}$$

where C_a = apparent capacitance, farads
C = actual capacitance, farads
L = inductance of capacitor, henrys
ω = 2π times frequency, cps

The differences between the apparent and the actual capacitances are negligible at medium frequencies but increase rapidly at higher frequencies, where the effect can be reduced by feeding the center of the stack of plates rather than the end. This construction is used in variable air capacitors intended for use as standards or for measurements at the higher radio frequencies.
FIG. 19. Equivalent circuit of air capacitor.

The power factor of a standard variable air capacitor at frequencies up to several megacycles is usually much higher at the low portion of the capacitance scale. As the frequency is raised, the power factor increases very rapidly with increase in scale setting.

33. Methods of Measuring Capacitance. There are two general methods of capacitance measurement: (1) absolute measurements in terms of other electrical or physical units, (2) comparison methods, where a capacitor of unknown capacitance is compared with a known calibrated capacitor. The absolute methods are not carried out at radio frequencies.

Among the simpler comparison methods may be mentioned those operating at an audio frequency or low radio frequency where the measuring device may be direct-reading. Such devices would include capacitor analyzers, bridges, and microfarad meters. Some of these devices are intended for quickly indicating capacitance and may not show more than two significant figures. Precision of measurement is sacrificed for speed in use. Such devices are extremely useful in some cases.
FIG. 20. Circuit for measuring capacitance.

There are a number of arrangements that may be used for capacitor calibrations at radio frequencies. These include the simple radio circuits shown in Figs. 20 and 21, r-f bridges, Q meters, and twin-T impedance-measuring circuits. The precision of measurement in any of the various methods cannot exceed that of the standard capacitor.
FIG. 21. Simple scheme for measuring capacitance.

A simple tuned circuit consisting of a coil and the capacitor under test is arranged with a double-throw switch so that the standard capacitor may be readily substituted. Resonance may be indicated by a sensitive meter coupled to the main coil by a few turns of wire. A crystal detector and 1-ma d-c meter make a very convenient indicating device. Power is supplied electromagnetically by a small vacuum-tube oscillator. The measurement circuit is shown in Fig. 20. The shielded side of the capacitor should be grounded. It is essential that the leads connecting the switch points to each capacitor be of the same

length in each case; otherwise the circuits will not have the same amount of inductance when one capacitor is substituted for the other. This will result in an error in the calibration. The coupling between the test circuit and the oscillators should be kept quite loose, which will be necessary if a sensitive resonance-indicating instrument is used.

If in the circuit shown in Fig. 20 a fixed inductor is used, the calibration will be made at various frequencies depending upon the capacitance for the different settings. A variable air capacitor of suitable size could be connected across the coil at *XX* and used to keep the resonance frequency the same for any setting of C_x. If such a circuit is carefully set up, no errors will result if the two circuits connected to C_x and C_s are similar. The frequency at which the measurements are made can be measured with a frequency meter. The frequency or frequency range over which a calibration is made should always be stated.

For rougher calibration work, the circuit shown in Fig. 21 may be used where C_s is tuned both with and without C_x in the circuit. It should be noted that the leads and switch connecting C_x to the circuit will introduce errors in the calibration.

The accuracy of this method can be greatly improved by careful arrangement and shortening of the leads connecting C_x to C_s. The switch should be replaced by a short wire, which by the least movement makes or breaks contact with the high-potential terminal of condenser C_x.

A method[1] of precision calibration of variable air capacitors at a single frequency has been described in which the unknown capacitor and the standard capacitor are alternately made a part of the oscillator furnishing the power. The method also offers a very precise means of measuring the change in capacitance with frequency of a mica capacitor.

The manufacturers of equipment for precise measurement of capacitance furnish instructions for use of their instruments. In general, the unknown capacitance is substituted for an equivalent capacitance in the standard capacitor.

The accuracy that can be attained in the measurement of a given capacitor depends upon a number of factors, among which are (1) the type of capacitor, *i.e.*, shielded or unshielded, (2) the length of leads employed in connecting the capacitor, (3) the physical dimensions of the capacitor, which also affect the length of leads, (4) the capacitance of the capacitor. Other factors that may be mentioned are accuracy of standard capacitor, ability of test capacitor to maintain capacitance value, and temperature effects.

A shielded capacitor is the only type that may be expected to maintain its capacitance value in subsequent use. The capacitance of an unshielded unit may readily be measured, but the value so obtained is affected by its position with respect to grounded panels or other objects, by the terminal that is grounded, lead length, etc., so that unshielded capacitors are not satisfactory where precise values of capacitance are required.

The length of leads, the size, and spacing affect the value of capacitance obtained. The leads should be made as short as possible. Corrections can be made for the leads, or their configuration can be given so that they could be duplicated if desired.

A capacitor of large proportions offers some difficulty because of the long connecting leads required for measurement. Above frequencies of 500 kc, lead corrections should be applied, or procedures used in which the leads are the same length for the standard and unknown capacitors.

Very small and very large capacitors are more difficult to measure accurately than those from 10 to 2,000 or 3,000 $\mu\mu$f. The measurement of very small capacitors is discussed in the next section. Very large capacitors are measured by connecting in series with a smaller capacitor, or by paralleling a number of smaller capacitors. In either case there may be sufficient "stray" capacitances to reduce the accuracy of the measurement.

[1] Hall, E. L., and W. D. George, Precision Condenser Calibration at Radio Frequencies, *Electronics*, **7**, 318, 1934.

34. Measurement of Very Small Capacitances. It has always been difficult to obtain agreement between various laboratories in the measurement of capacitances of 5 μμf or smaller. There have been several reasons for this, including differences in the standards of the various laboratories, differences in lead length, size, and spacing, and stray capacitances. Perhaps the greatest difficulty was in the magnitude of the quantity being measured. Consider a capacitance of 1.00 μμf. A 2-in. length of No. 10 wire 0.4 in. above a ground plate would have this capacitance.[1] A measurement to 1 per cent (0.01 μμf) would, therefore, require very exact positioning of leads, or the use of a jig to ensure exact placement of the condenser under test.

Considerable difficulty was experienced by tube manufacturers early in the recent war, in supplying tubes with interelectrode capacitance within the limits prescribed by the Navy. The difficulty was overcome by the adoption of special test equipment and special measurement techniques.

A special bridge[2] has been described for measuring interelectrode capacitances at 465 kc. The conductance and capacitance can be measured in terms of standard capacitors having much larger values than the components being measured. Five decimal divisors are available so that capacitances can be read to 1/100,000 μμf. Bridge balance is sensitive to that amount.

Very small capacitance values or changes in capacitance can be determined by measuring the change in frequency when the unknown capacitance is added to the tuning capacitance of an oscillator. The method described in a previous reference can be adapted by slight rearrangement so as to measure the a-f difference between an auxiliary standard oscillator and the measuring oscillator without the small capacitance and with it in circuit. The small capacitance or change in capacitance is given by the following equation:[3]

$$\Delta C_x = C_0\left[\left(\frac{f_0}{f_1}\right)^2 - 1\right]$$

where ΔC_x = small capacitance, μμf
C_0 = capacitance of oscillator before ΔC_x was added and includes all capacitances that produce the frequency f_0
f_1 = frequency of oscillator with both C_0 and ΔC_x in parallel

The value of C_0 must be measured. This is done in a similar manner by substituting a known capacitor for ΔC_x and measuring the frequency change with an oscillator.

Capacitance differences can be very precisely measured if a standard is available with a sufficiently finely divided scale. Such standards have taken cylindrical form with a concentric rod, movable longitudinally by means of a fine screw and equipped with a scale to indicate the position of the rod. The change in capacitance can be calculated from the following equation:[4]

$$C = \frac{0.613}{\log_{10}(b/a)}$$

where C = capacitance, μμf per in.
b = inside diameter of cylinder, in.
a = diameter of inner rod, in.

35. Methods of Measuring Capacitor Resistance and Power Factor and Dielectric Constant of Insulating Materials at Radio Frequencies. Measurements of capacitor resistance and power factor of insulating materials are made in practically the same manner, as the sample of insulating material is prepared so as to form a capacitor. Methods of measuring capacitor resistance[5] and power factor of insulating materials[6]

[1] Terman, F. E., "Radio Engineers' Handbook," p. 114, McGraw-Hill, 1943.

[6] Methods of Measurement of Properties of Electrical Insulating Materials, *Nat. Bur. Standards Sci. Paper* 471.

have been given in publications of the National Bureau of Standards. The ASTM has several standard methods of testing electrical insulating materials for power factor and dielectric constant.[1]

The circuit shown in Fig. 22 may be used for measurements of resistance, power factor, and dielectric constant. Assuming that the power factor of a sample of insulating material is to be measured, the sample in sheet form is made into a capacitor of capacitance between 100 and 1,000 $\mu\mu$f, as represented by C_x (Fig. 22). The remainder of the circuit consists of the coil L, thermoelement T, and double-pole, double-throw switch S, in which resistors R may be inserted. The galvanometer G gives deflections
FIG. 22. Circuit for measuring properties of insulators.

that are proportional to the square of the current flowing in the circuit LTC_xR, as electromagnetically induced from the r-f oscillator O.

The deflections of galvanometer G are noted for several values of inserted resistance R and for the case when R is a link of practically zero resistance. Using the "zero resistance" deflection and the deflection for a known value r of resistance inserted in switch S, the resistance R_T of the total circuit LTC_xR is given by

$$R_T = \frac{r}{\sqrt{\frac{d_0}{d_1}} - 1}$$

The average of the values of R_T calculated for various values of r should be taken as the resistance of the complete circuit. The resistance R_S of the circuit when C_S is substituted for C_X should be obtained in the same manner. The resistance R_X of the capacitor C_x is then given by $R_x = R_T - R_S$. It is essential for this measurement that the two parts of the circuit which are interchanged should be as nearly identical as possible.

After the resistance R_x of the insulating material capacitor is obtained, the power factor or phase difference can be calculated from the equations given above. The dielectric constant K can be calculated from the equation $K = Ct/0.0885S$, where C = capacitance of sample in micromicrofarads, t = thickness of sample in centimeters, and S = area of smaller plate in square centimeters. The capacitance is known, as given by C_S, and the area of one plate and the thickness of the sample can easily be measured.

The method described above operates satisfactorily at frequencies from 100 to 1,500 kc.

ASTM method D150-47T gives details for the procedure for eight methods of

[1] Tentative Methods of Test for Power Factor and Dielectric Constant of Electrical Insulating Materials, designation D150-47T; Standard Method of Test for Power Factor and Dielectric Constant of Natural Mica, designation D1082-51T.

measuring dielectric constant and power factor of solid and liquid electrical insulating materials. These include five bridge techniques and three resonance techniques which are applicable in the range of about 25 cps to a few hundred megacycles.

Transmission-line and concentric-line methods of impedance measurement can be adapted to power factor and dielectric constant measurements of dielectrics, but there are practical difficulties in the preparation of samples which limit the usefulness of these methods. A resonant-cavity method[1] has been described operating in the range from 100 to 1,000 Mc which is claimed to have many advantages in use, such as simplicity and rapidity. Several cavities are required, each covering a frequency ratio of 1 to 1.5. Dielectric samples in disk form up to 1½ in. in diameter and from 0.05 to ¼ in. thick are used. From measurements made with the sample in and out of the cavity, the dissipation factor and the dielectric constant are obtained by simple calculation.

CHAPTER 5

COMBINED CIRCUITS OF L, C, AND R

By W. F. Lanterman[1]

1. Transient and Steady-state Currents. When a voltage is suddenly applied to a circuit, the current assumes a transient state for a brief interval, then gradually settles down to a steady-state condition which it maintains until the voltage is interrupted or changed. Relations for computing transient and steady-state currents and voltages in LCR circuits are given in the following paragraphs. The curves shown for current and voltage are typical for each case but are drawn for particular values of the arbitrary constants.

TRANSIENT CURRENTS IN LCR CIRCUITS

2. Symbols Used in Transient Expressions. In the transient exrpessions given in Secs. 3 to 5, the following symbols will be used:

L = inductance, henrys
C = capacitance, farads
R = resistance, ohms
T = time constant, sec; time, sec, for current or voltage to reach $1/\epsilon$ or approximately 36.8 per cent of its initial value if decreasing; or $1 - (1/\epsilon)$, or approximately 63.2 per cent of its final value if increasing
i = instantaneous current, amp, at time t
e = instantaneous voltage, volts, at time t
e_c = instantaneous capacitor voltage
e_L = instantaneous inductor voltage
t = time, sec, after starting
I = steady-state d.c., amp
E = maximum value of a-c voltage, volts
V = steady-state d-c voltage, volts
Q = capacitor charge, coulombs
Z = a-c impedance, ohms
$= \sqrt{R^2 + \left(\omega L - \frac{1}{\omega C}\right)^2}$ for LCR circuit
$= \sqrt{R^2 + (\omega L)^2}$ for LR circuit
$= \sqrt{R^2 + (1/\omega C)^2}$ for RC circuit
f = frequency of applied a.c., cps
ω = angular velocity of applied a.c., radians per sec $= 2\pi f$
f_1 = natural frequency of oscillatory circuit LCR, cps
ω_1 = natural angular velocity of oscillatory circuit LCR, radians per sec $= 2\pi f_1$
W_R = energy, joules, dissipated in R during transient state
W_L = energy, joules, stored by or lost by L during transient state
W_C = energy, joules, stored by or lost by C during transient state
θ = phase angle of a-c voltage at $t = 0$, *i.e.*, when switch is closed
ϕ = phase angle of impedance as defined for each case
ϵ = 2.718 (base of natural logarithms)
α and β = (defined in Sec. 5)

[1] National Broadcasting Co., Inc., Chicago, Ill.

3. *RC* Circuit Transients.

NOTE: The following formulas for i in RC circuits are not true for extremely small values of t. For very small t, the L of the circuit, no matter how small, limits i, and the relations of Sec. 5 for LCR circuits must be applied. This is especially important for short pulses or high frequencies, where small values of t are involved. The equations for RC circuits neglect the effects of L for small values of t, but the figures show true current forms.

FIG. 12.

$$i^* = \underline{\frac{E}{Z}\sin(\omega t + \theta - \phi)} - \frac{E}{Z}\sin(\theta - \phi)\epsilon^{-(Rt/L)}$$

$$e_L^* = \underline{\frac{E}{Z}\omega L\cos(\omega t + \theta - \phi)} + \frac{E}{Z}R\sin(\theta - \phi)\epsilon^{-(Rt/L)}$$

$$e_R^* = \underline{\frac{ER}{Z}\sin(\omega t + \theta - \phi)} - \frac{ER}{Z}\sin(\theta - \phi)\epsilon^{-(Rt/L)}$$

$$\text{Magnitude of } \phi = \tan^{-1}\left(\frac{\omega L}{R}\right)$$
There is no transient if $\theta = \phi$ or if $(\theta - \phi) = 180°$.

* Underscored terms represent steady-state values; remaining term or terms are the transients.

5. *LCR* Circuit Transients. 1. *D-c Voltage V Suddenly Applied to Deenergized LCR. General Solutions:*
Fig. 13.

$$i = \frac{V}{2\beta L}\epsilon^{-\alpha t}(\epsilon^{\beta t} - \epsilon^{-\beta t}) = \frac{V}{\beta L}\epsilon^{-\alpha t}\sinh \beta t$$

$$e_c{}^* = V\left[\underline{1} - \epsilon^{-\alpha t}\left(\cosh \beta t + \frac{\alpha}{\beta}\sinh \beta t\right)\right]$$

$$e_L = V\epsilon^{-\alpha t}\left(\cosh \beta t - \frac{\alpha}{\beta}\sinh \beta t\right)$$

$$e_R = 2V\frac{\alpha}{\beta}\epsilon^{-\alpha t}\sinh \beta t$$

where

$$\alpha = \frac{R}{2L}$$

$$\beta = \sqrt{\frac{R^2}{4L^2} - \frac{1}{LC}} = \frac{1}{2L}\sqrt{R^2 - \frac{4L}{C}}$$

There are three special cases, depending upon whether R^2 is greater than, less than, or equal to $4L/C$:

Case I. Aperiodic current, when $R^2 > 4L/C$ (β is real). i, e_c, e_L, and e_R are determined directly from the above general solutions by numerical substitution for α and β.

At $t_1 = \left(\frac{1}{2\beta}\log_\epsilon \frac{\alpha + \beta}{\alpha - \beta}\right)$ sec $= \left(\frac{1}{\beta}\tanh^{-1}\frac{\beta}{\alpha}\right)$ sec, i and e_R reach maxima, then slowly decay to zero. At the same time, t_1, e_L becomes zero and thereafter becomes negative, reaching a minimum at $t_2 = \left(\frac{1}{\beta}\log_\epsilon \frac{\alpha + \beta}{\alpha - \beta}\right)$ sec $= \left(\frac{2}{\beta}\tan^{-1}\frac{\beta}{\alpha}\right)$ sec, which is twice the time required for i to reach maximum.
Fig. 14. Case I. Aperiodic.
Fig. 15. Case II. Critical damping

Case II. Critical damping, when $R^2 = 4L/C$ ($\beta = 0$).

$$i = \frac{V}{L}t\epsilon^{-\alpha t}$$

$$e_c{}^* = V[\underline{1} - \epsilon^{-\alpha t}(1 + \alpha t)]$$

$$e_L = V\epsilon^{-\alpha t}(1 - \alpha t)$$

$$e_R = 2\,V\alpha t\epsilon^{-\alpha t}$$

At $t_1 = 1/\alpha = 2L/R$ sec, i reaches a maximum of $0.736V/R$ and e_R reaches a maximum of $0.736V$. At the same time, t_1, e_L becomes zero and thereafter becomes negative, reaching a minimum of $-0.1353V$ at $t_2 = 2/\alpha$ sec, which is twice t_1.

* Underscored terms represent steady-state values; remaining term or terms are the transients.

Case III. Oscillatory current, when $R^2 < 4L/C$ (β is imaginary).

$$i = \frac{V}{\omega_1 L}\epsilon^{-\alpha t}\sin\omega_1 t$$

where $\omega_1 = \sqrt{\frac{1}{LC} - \frac{R^2}{4L^2}} = 2\pi f_1$

$$e_c{}^* = V\left[\underline{1} - \epsilon^{-\alpha t}\left(\cos\omega_1 t + \frac{\alpha}{\omega_1}\sin\omega_1 t\right)\right]$$

$$e_L = V\epsilon^{-\alpha t}\left(\cos\omega_1 t - \frac{\alpha}{\omega_1}\sin\omega_1 t\right)$$

$$e_R = 2V\epsilon^{-\alpha t}\frac{\alpha}{\omega_1}\sin\omega_1 t$$

NOTE: $\frac{\alpha}{\omega_1} = \sqrt{\frac{R^2C}{4L - R^2C}}$.

FIG. 16. Case III. Oscillatory.

At $t_1 = 1/4f_1$ sec, approximately, i reaches a maximum and at $t_2 = 1/2f_1$ sec, e_c reaches a maximum. e_L is maximum at $t = 0$. Beyond their respective maxima all four quantities oscillate at frequency f_1, with amplitudes slowly decreasing to zero, except e_c, which approaches V.
Superimposed Curves. Curves for i in the three special cases are shown superimposed for direct comparison in Fig. 17. The conditions for all three cases are identical except that R is varied to alter the value of α.
FIG. 17. Superimposed current curves for d.c. in LCR circuit.

2. *A-c Voltage e Suddenly Applied to Deenergized LCR.*

Applied voltage $e = E\sin(\omega t + \theta)$
FIG. 18.

There are three special cases, depending upon the ratio

$$\alpha = R/2L$$

Case I. Aperiodic current, when $\alpha^2 = R^2/4L^2 > 1/LC$ (β is real).

$$i^* = \underline{\frac{E}{Z}\sin(\omega t + \theta - \phi)} + \frac{E}{Z}\frac{1}{2\beta L}\left[L(\alpha - \beta)\sin(\theta - \phi) - \frac{1}{\omega C}\cos(\theta - \phi)\right]\epsilon^{-(\alpha-\beta)t} - \frac{E}{Z}\frac{1}{2\beta L}\left[L(\alpha + \beta)\sin(\theta - \phi) - \frac{1}{\omega C}\cos(\theta - \phi)\right]\epsilon^{-(\alpha+\beta)t}$$
FIG. 19. Case I. Aperiodic.

* Underscored terms represent steady-state values; remaining term or terms are transients.

Case II. Critical damping, when $\alpha^2 \equiv R^2/4L^2 = 1/LC$ ($\beta = 0$).

$$i^* = \underline{\frac{E}{Z}\sin(\omega t + \theta - \phi)} + \frac{E}{Z}\left[(\alpha t - 1)\sin(\theta - \phi) - \frac{1}{L\omega C}\cos(\theta - \phi)\right]\epsilon^{-\alpha t}$$
FIG. 20. Case II. Critical damping.

Case III. Oscillatory current, when $\alpha^2 = R^2/4L^2 < 1/LC$ (β is imaginary).

$$i^* = \underline{\frac{E}{Z}\sin(\omega t + \theta - \phi)} - \frac{E}{Z}\epsilon^{-\alpha t}\left[\sin(\theta - \phi)\cos\omega_1 t + \frac{1}{\omega_1 L\omega C}\cos(\theta - \phi)\sin\omega_1 t - \frac{R}{2\omega_1 L}\sin(\theta - \phi)\sin\omega_1 t\right]$$
FIG. 21. Case III. Oscillatory.

6. Time Constants. Time constant is an arbitrary factor used to gage the exponential rate of transient current or voltage increase in a circuit containing reactance and resistance in series. It denotes only the relative duration of the transient, and no special physical phenomenon occurs when the transient has existed for a length of time equal to the time constant.

For exponentially increasing quantities the time constant is the time in seconds required for the quantity to attain a value equal to $1 - (1/\epsilon) = 0.63212$ (or 63.2 per cent, approximately) of its final value. For exponentially decreasing quantities, it is the time in seconds required for the quantity to attain $1/\epsilon = 0.36788$ (or 36.8 per cent, approximately) of its initial value.

In series LR circuits, the time constant is $T = L/R$ sec; in series RC circuits, $T = RC$ sec, where R is in ohms, L in henrys, and C in farads (see Secs. 3 and 4).

7. Logarithmic Decrement. The logarithmic decrement is the natural logarithm of the ratio of amplitudes of two successive oscillations (of the same polarity) of a damped wave train. In terms of L, R, C, and Q, the decrement is

$$\delta = \frac{2\pi R}{\sqrt{4(L/C) - R^2}} = \frac{R}{2Lf_r} = \frac{\pi}{Q} \quad (1)$$

where f_r is the resonant frequency of the circuit, and $Q = \omega_r L/R$.

FIG. 22. Typical networks used with pulses.

8. Pulsed Circuits. In television synchronizing systems and other timing circuits the input voltage applied to networks of the types shown in Fig. 22 consists of a series of one or more d-c pulses of the forms shown in Fig. 23. Idealized, the pulse voltage is zero up to a given instant and, at each instant thereafter up to time $= P$ sec, it has a succession of finite values determined by some given pulse form. At P sec, the voltage drops instantly to zero and remains equal to zero until the start of the next pulse. The networks and pulses in Figs. 22 and 23 are typical only; any

* Underscored terms represent steady-state values; remaining term or terms are the transients.

one of an infinite number of pulse shapes may be applied to any one of an infinite number of networks.

Solutions for the output voltage or current are obtained by considering the pulse as creating a transient condition starting at $t = 0$, followed by a new transient condition (to restore the input voltage to zero) starting at $t = P$. If the pulse form can be expressed as a function of t, $e = f(t)$, the output voltage or current is obtained by setting up and solving the differential equations in which the sum of the instantaneous voltage drops in the circuit is equated to $f(t)$. At $t = P$ there is a discontinuity where e suddenly decreases to zero, if the pulse shape is not such that e is already zero when $t = P$. This requires solution of a new differential equation in which the voltage drops existing in the circuit at $t = P$ are equated to zero. This equation must take into account the energy stored in the inductances and capacitances at the instant when $t = P$. Unfortunately, each pulse circuit and each pulse shape is a special case, and results cannot be generally formulated except for typical examples.

FIG. 23. Typical pulse forms.

Example: For a saw-tooth pulse of the form of Fig. 23*b* applied to the *LR* network of Fig. 22*d* the differential equation applying between $t = 0$ and $t = P$ is

$$L\frac{di}{dt} + iR = Vat \tag{2}$$

in which $i = 0$ when $t = 0$, and V and a are defined in Fig. 25. The solution is

$$i = \frac{Vat}{R} - \frac{VaL}{R^2}[1 - \epsilon^{-(Rt/L)}] \tag{3}$$

and the output voltage is

$$e_L = L\frac{di}{dt} = \frac{VaL}{R}[1 - \epsilon^{-(Rt/L)}] = V_n[1 - \epsilon^{-(t/nP)}] \tag{4}$$

where symbols are as defined in Fig. 25.

At $t = P$ the circuit is short-circuited and corresponds to an *LR* circuit carrying d-c I and suddenly short-circuited as in Sec. 4. The voltage equation for $t > P$ is

$$L\frac{di}{d(t-P)} + iR = 0 \tag{5}$$

in which $i = I$ when $t = P$. The solution is

$$i = I\epsilon^{-[R(t-P)/L]} \tag{6}$$

and the output voltage is

$$e_L = L\frac{di}{d(t-P)} = -IR\epsilon^{-[R(t-P)/L]} = -V[1 - n(1 - \epsilon^{-1/n})]\epsilon^{-(t-P)nP} \tag{7}$$

In any practical case, the voltage drop in the source and the effect of the load upon the pulse output cannot be ignored. That is, the L's, C's, and R's in the source and load must be considered as parts of the network. To preserve the pulse shape through a network, it is customary to employ a low-impedance source and a high-impedance load.

Figures 24 to 27 show output voltages for the four pulse forms of Fig. 23 applied to

the networks of Fig. 22. In this case, it is assumed that the input is short-circuited at $t = P$ and thereafter, also that the load impedance is very large compared to that of the network element from which the output voltage is taken. It is also assumed that the Q's of L and C are sufficiently large so that their resistances are negligible as compared to the R's of the network.

Symbols and relations used:
t = time, sec, from start of pulse
T = time constant, sec
P = pulse duration, sec
V = maximum pulse voltage (input)
n = T/P (or $T = nP$)

V e = V (t<P)
O time → P
Applied voltage pulse

Fig. 24. Equations and pulse forms for output voltage of pulsed networks with rectangular pulses of duration P sec applied.

The exponential pulse forms are chiefly of interest when the origin of the input pulse to a particular network is a preceding network whose output pulse has the exponential form. For example, the output pulse is exponential when a rectangular pulse is applied to any of the four networks of Fig. 22.

9. Differentiating and Integrating Networks. Circuits of the types of Fig. 22*c* and *d*, in which the time constant is made very small as compared to the pulse length,

produce output voltage pulses that are approximately the derivatives of the input voltage pulses, as shown in Fig. 28. From this fact, they derive the name *differentiating networks.*

Similarly, circuits of the types of Fig. 22*a* and *b*, in which the time constant is made

Circuit		e = (series C, shunt R)	e = (series R, shunt L)	e = (series R, shunt C)	e = (series L, shunt R)
Time constant		RC	L/R	RC	L/R
e_{out}	$t<P$	$Vn(1-\epsilon^{-\frac{t}{nP}})$		$V\left[\frac{t}{P}-n(1-\epsilon^{-\frac{t}{nP}})\right]$	
	$t=P$	$Vn(1-\epsilon^{-\frac{1}{n}})$		$V\left[1-n(1-\epsilon^{-\frac{1}{n}})\right]$	
	$t>P$	$-V\left[1-n(1-\epsilon^{-\frac{1}{n}})\right]\epsilon^{-\frac{t-P}{nP}}$		$V\left[1-n(1-\epsilon^{-\frac{1}{n}})\right]\epsilon^{-\frac{t-P}{nP}}$	
e_{out}	$T \ll P$, $n \to 0$	V- ; O t → P (Differentiating)		V- ; O t → P	
	$T = P$, $n = 1$	V- ; O t → P		V- ; O t → P	
	$T \gg P$, $n \to \infty$	V- ; O t → P		V- ; O t → P (Integrating)	

Symbols and relations used:
- t = time, sec, from start of pulse
- T = time constant, sec
- P = pulse duration, sec
- V = maximum pulse voltage (input)
- n = T/P (or $T = nP$)
- a = arbitrary constant

V- ; O ; P ; time →

$e = Vat_{(t<P)}$ $V = aP$

FIG. 25. Equations and pulse forms for output voltage of pulsed networks with saw-tooth pulses of duration P sec applied.

large compared to the pulse duration, produce output voltage pulses that are approximately the integrals of the input voltage pulses, as shown in Fig. 29. This type of network is called an *integrating network.*

10. "Constant-current" RC Circuit. In a series RC circuit as shown in Fig. 30*a*, when C is discharged through R, the current varies logarithmically with time (see

Fig. 4, Sec. 3). For pulses of short duration relative to the time constant R_0C an approximation to constant current is obtained by inserting the network L-R as in Fig. 30*b*, where the time constant L/R is made much larger than the pulse duration time. L and R are determined by the relation $L = R^2C$, and the resulting current is

FIG. 26. Equations and pulse forms for output voltage of pulsed networks with exponentially increasing pulses of duration P sec applied.

essentially independent of the load resistance R_0 except in magnitude. The actual variation of the value of i during such a pulse is reduced to about 10 per cent of the variation obtained with the simple R_0C circuit.[1]

[1] Fundingsland, O. T., and G. J. Wheeler, *Electronics*, November, 1946, p. 130.

Symbols and relations used:

t = time, sec, from start of pulse
T = time constant, sec
P = pulse duration, sec
V = maximum pulse voltage (input)
n = T/P (or $T = nP$)
a = arbitrary constant
α = aT

V e = $V\epsilon^{-at}$ (t<P)
0 time→ P

STEADY-STATE CURRENTS IN *LCR* CIRCUITS

11. *Q* in *LCR* Circuits. By definition,

$$Q = \frac{\text{volt-amp stored}}{\text{watts dissipated}} = \frac{X}{R} \tag{8}$$

Q **of a coil:**

$$Q = \frac{\omega L}{R} = \frac{2\pi f L}{R} \tag{9}$$
FIG. 28. Pulse forms produced by differentiating networks.
FIG. 29. Pulse forms produced by integrating networks.
FIG. 30. Modified RC circuit for short pulses of constant current from discharge of C.

Q of a capacitor:

$$Q = \frac{1}{\omega CR} = \frac{1}{2\pi fCR} \tag{10}$$

Q of a circuit:

$$Q = \frac{\omega L}{R_t} \quad \text{or} \quad \frac{1}{\omega CR_t} \tag{11}$$

where R_t is the total resistance and L or C is the total inductance or capacitance in the circuit. If both L and C are present, $\omega = 2\pi \times$ the resonance frequency.

As a rule, the Q of a coil or capacitor varies less with frequency than does the effective resistance. Thus the assumption that Q is constant is usually more nearly accurate than the assumption that R is constant in expressions for tuned circuits. Expressions containing Q are still approximations, however, and are often loosely used without regard for the fact that Q actually does vary with frequency. Such expressions are most nearly correct for large values of Q (of the order of 100) and when the frequency range is small.

In general, the "sharpness" of resonance of a circuit increases with increased values of Q.

12. A-c Impedance Relations. For applied voltage, $e = E \sin \omega t$, $\omega = 2\pi f$, f = frequency in cycles.

$$Z = \frac{E}{I} = R + jX = |Z| \,\underline{/\phi} \quad \text{ohms} \tag{12}$$

$$Z = \sqrt{R^2 + X^2} \quad \text{ohms} \tag{13}$$

$$\phi = \tan^{-1}\frac{X}{R} = \cos^{-1}\frac{R}{Z} = \sin^{-1}\frac{X}{Z} \quad \text{radians or deg} \tag{14}$$

FIG. 31. Equivalent impedances of series combinations of *L*, *C*, and *R*.

Reactance of C:

$$X_C = -\frac{1}{\omega C} = -\frac{1}{2\pi f C} \quad \text{ohms} \tag{15}$$

Reactance of L:

$$X_L = \omega L = 2\pi f L \quad \text{ohms} \tag{16}$$

Impedance of LCR in series:

$$Z = R + j\left(\omega L - \frac{1}{\omega C}\right) \quad \text{ohms} \tag{17}$$

Impedance in series:

$$Z_0 = Z_1 + Z_2 + Z_3 + \cdots \qquad \text{(see Fig. 31)} \tag{18}$$

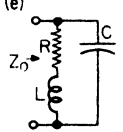
Two impedances in parallel:

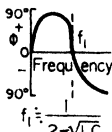
$$Z_0 = \frac{Z_1 Z_2}{Z_1 + Z_2} \tag{19}$$

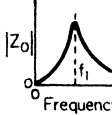
Three impedances in parallel:

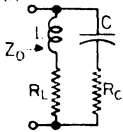
$$Z_0 = \frac{Z_1 Z_2 Z_3}{Z_1 Z_2 + Z_1 Z_3 + Z_2 Z_3} \tag{19a}$$

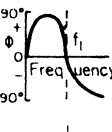
Any number n of impedances in parallel:

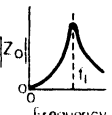
$$Z_0 = \frac{1}{\dfrac{1}{Z_1} + \dfrac{1}{Z_2} + \dfrac{1}{Z_3} + \cdots + \dfrac{1}{Z_n}} \tag{19b}$$
FIG. 32a. Equivalent impedances of parallel combinations of L, C, and R.












$$Z_0 = \frac{R_1(R_2^2+X_2^2)+R_2(R_1^2+X_1^2)+j\left[X_1(R_2^2+X_2^2)+X_2(R_1^2+X_1^2)\right]}{(R_1+R_2)^2+(X_1+X_2)^2}$$

$X_L = 2\pi fL$ ohms $\qquad X_C = \frac{10^6}{2\pi fC}$ ohms (C in mfds.)

Circuit	Phase angle	Magnitude of Z_0	Algebraic formulas

(f) Resistance and inductance in series and in parallel with capacitance and resistance in series	$f_1 \doteq \frac{1}{2\pi\sqrt{LC}}$ $Q > 1$ Not valid for $Q \leqq 1$		$Z_0 = \frac{(R_LA+R_CB)+j(X_LA-X_CB)}{(R_L+R_C)^2+(X_L-X_C)^2}$ $A = (R_C^2+X_C^2)$, $B = (R_L^2+X_L^2)$ $\lvert Z_0\rvert = \frac{\sqrt{(R_LA+R_CB)^2+(X_LA-X_CB)^2}}{(R_L+R_C)^2+(X_L-X_C)^2}$ $\doteq \frac{L}{(R_L+R_C)C}$ when $X_L = X_C$ and R_L and R_C are small $\Phi = \tan^{-1}\frac{X_LA-X_CB}{R_LA+R_CB}$ $\doteq 0$ when $X_L = X_C$ and R_L and R_C are small

FIG. 32b. Equivalent impedances of parallel combinations of L, C, and R.

Some commonly used parallel combinations of LCR are shown in Fig. 32a and b, with their impedance and phase relations.

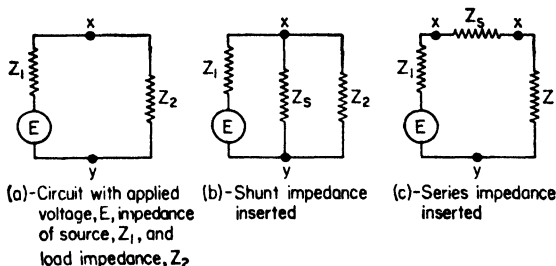
13. Loss Due to Inserting Series or Shunt Impedance in Audio Circuits. In audio circuits, attenuation-frequency characteristics are often purposely modified by the insertion of corrective impedances such as equalizers, "tone controls," and scratch filters. The following formulas give the insertion losses in such cases:


FIG. 33. Shunt and series impedances inserted in audio-frequency circuits.

1. *Shunt Impedance.* The loss due to inserting a shunt impedance Z (Fig. 33a and b) is

$$L = 20 \log_{10}\left(1 + \frac{Z_1Z_2}{Z_s(Z_1+Z_2)}\right) \quad \text{db} \tag{20}$$

The shunting impedance can usually be located at a point in the circuit where the imped-

ances Z_1 and Z_2 are matched and where each is substantially a pure resistance through the range of frequencies involved. Then, letting $Z_1 = Z_2 = R_0$, the loss is

$$L = 20 \log_{10} \left| \frac{2Z_s + R_0}{2Z_s} \right| \text{ db} = 20 \log_{10} \sqrt{1 + \frac{\cos \phi}{K} + \frac{1}{4K^2}} \text{ db} \qquad (20a)$$

where $K = |Z_s|/R_0$ and ϕ is the phase angle of Z_s. For various values of K and ϕ the loss can be read from the curve (Fig. 34).
FIG. 34. Transmission loss due to insertion of shunt or series impedance.

2. *Series Impedance.* The loss in decibels due to inserting a series impedance Z_s (Fig. 33*a* and *c*) is

$$L = 20 \log_{10} \left(\frac{Z_1 + Z_2 + Z_s}{Z_1 + Z_2} \right) \text{ db} \qquad (21)$$

The series impedance can usually be inserted at a point in the circuit where the impedances Z_1 and Z_2 are matched and where each is substantially a pure resistance through the range of frequencies involved. Then, letting $Z_1 + Z_2 = R_0$, the loss is

$$L = 20 \log_{10} \left| \frac{R_0 + Z_s}{R_0} \right| \quad \text{db}$$

$$= 20 \log_{10} \sqrt{1 + 2K \cos \phi + K^2} \quad \text{db} \tag{21a}$$

where $K = |Z_s|/R_0$ and ϕ is the phase angle of Z_s. The loss can be read from Fig. 34 for various values of K and ϕ.

14. Series Resonance. With L and C in series, resonance is the condition where $X_L = X_C$ and current is maximum. In the ideal resistanceless circuit, the impedance would be zero at resonance; so series resonance is often referred to as a "zero" in network theory. The presence of resistance in an actual physical circuit does not affect the resonance frequency for a given L and C.

Resonance frequency:

$$f_r = \frac{1}{2\pi \sqrt{LC}} \tag{22}$$

where f is in cycles, L in henrys, and C in farads.

Impedance at resonance:

$$Z_r = R_r \quad \text{ohms} \tag{23}$$

Impedance at any frequency, f_1:

$$Z_1 = R_1 + j2\pi L \left(\frac{f_1^2 - f_r^2}{f_1} \right) = |Z_1| \underline{/\phi_1} \quad \text{ohms} \tag{24}$$

$$|Z_1| = \sqrt{R_1^2 + 4\pi^2 L^2 \left(\frac{f_1^2 - f_r^2}{f_1} \right)^2} \tag{25}$$

$$\phi_1 = \tan^{-1} \frac{X_1}{R_1} = \tan^{-1} \left[\frac{2\pi L(f_1^2 - f_r^2)}{f_1 R_1} \right] \tag{26}$$

Subscript$_{(r)}$ denotes values at resonance, and subscript$_{(1)}$ values at any frequency f_1.

Impedance in terms of Q:

Either of two conditions may be assumed: (1) Q is constant as frequency varies; (2) R is constant as frequency varies. Neither is exactly true in any practical case because R actually varies with the frequency in a complex manner. Expressions in terms of Q, however, give fair approximations if $Q = 10$ or more and are, therefore, useful.

The differences for impedance between constant R and constant Q are a few per cent in impedance near resonance, for Q on the order of 10. For large Q and frequencies farther from resonance, the impedances by either assumption tend to become equal. The differences in phase-angle results are largest at frequencies farthest from resonance and for small Q's. Near resonance and with large values of Q, the values by both assumptions approach equality.
FIG. 35. (a) Series-resonant circuit and (b) current vs. frequency for constant E_0.

For *constant R:*

$$R = \frac{\omega_r L}{Q_r} = \frac{\omega_1 L}{Q_1} \tag{27}$$

$$\frac{|Z_1|}{\omega_r L} = \sqrt{\frac{1}{Q_r^2} + n^2 + \frac{1}{n^2} - 2} \tag{28}$$

$$\phi_1 = \tan^{-1}\left[Q_r\left(n - \frac{1}{n}\right)\right] \tag{29}$$

where $n = f_1/f_r$.

For *constant Q:*

$$Q = \frac{\omega_r L}{R_r} = \frac{\omega_1 L}{R_1}$$

$$\frac{|Z_1|}{\omega_r L} = \sqrt{\frac{n^2}{Q^2} + n^2 + \frac{1}{n^2} - 2} \tag{30}$$

$$\phi_1 = \tan^{-1}\frac{Q}{n}\left(n - \frac{1}{n}\right) \tag{31}$$

where $n = f_1/f_r$.

Subscript$_{(r)}$ denotes values at resonance, and subscript$_{(1)}$ values at any frequency f_1.

At resonance, the voltage drop (E_L) across L is numerically equal to the voltage drop (E_C) across C. In terms of applied voltage E_0 when $Q > 25$,

$$|E_L| = |E_C| = QE_0$$

or
$$Q = \frac{|E_C|}{E_0} \tag{32}$$

Fig. 36. Direct-reading Q meter.

The latter equation is the basis of a direct-reading Q meter illustrated in Fig. 36. The inductance L_x to be measured is connected in series with a low-loss variable capacitor C_x. Voltage E_0 is applied from a constant-voltage variable-frequency oscillator terminated in a very small resistance R_0. The frequency and series capacitances are adjusted for series resonance. A high-input-impedance vacuum-tube voltmeter
Fig. 37. Parallel-resonant circuit and characteristics for constant E_0 applied.

reads the series capacitor voltage $|E_C|$ and may be calibrated directly in terms of Q from Eq. (32), the input voltage being known and constant. In precision instruments, correction factors are applied to eliminate the loading effects of R_0 and the voltmeter impedance, and of the distributed capacitance C_s of the coil.

15. Parallel or Antiresonance. Resonance in parallel LC circuits, often called "antiresonance," or a "pole" of impedance, corresponds approximately to the con-

dition of maximum circulating current, or to maximum impedance between the terminals, as indicated in Fig. 37. Exact analysis, in each case based on slightly differing assumptions, yields various equations for the resonance frequency, all of which differ from each other by only small amounts. Those most useful in com-

NOTES: The double rules in Cols. 1 and 4 indicate that the decimal point in Cols. 2 and 5 is at the double rule; the single rules in Cols. 3 and 6 indicate that the decimal point in Cols. 2 and 5 is at the first single rule. Thus, the LC product for 100 cycles (Col. 1) is 2,533,030 (Col. 2) when the units are μμf and h; or is 2.533030 (Col. 5) if the units are μf and h (Col. 6).

For frequencies not listed, linear interpolation may be used for accuracies of 0.1 %. For higher accuracies, $LC = 253303/f^2$, neglecting decimals.

munications work are listed below. In all cases, the units are ohms, henrys, farads, and cycles.

1. *Free Oscillation Resonance* (R_C negligible).

$$f_r = \frac{1}{2\pi\sqrt{LC}}\sqrt{1 - \frac{R_L^2C}{4L}} \tag{33}$$

This is the natural frequency of oscillation in a parallel circuit excited by a single pulse. (See Sec. 5 also.)

2. *L Variable and Adjusted for Maximum* $|Z_0|$* (R_C negligible). If R_L is constant as L varies,

$$f_r = \frac{1}{2\pi\sqrt{LC}}\sqrt{1 + \frac{R_L^2C}{L}} \tag{34}$$

If L/R_L is constant as L varies,

$$f_r = \frac{1}{2\pi\sqrt{LC}} \tag{35}$$

3. *Frequency Variable and Adjusted for Maximum* $|Z_0|$ (R_C negligible).

$$f_r = \frac{1}{2\pi\sqrt{LC}}\sqrt{\sqrt{1 + \frac{2R_L^2C}{L}} - \frac{R_L^2C}{L}} \tag{36}$$

4. *C Variable and Adjusted for Maximum* $|Z_0|$ (R_C negligible).

$$f_r = \frac{1}{2\pi\sqrt{LC}}\sqrt{1 - \frac{R_L^2C}{L}} \tag{37}$$

In this case, the phase angle of Z_0 is zero at resonance (Z_0 = pure resistance), and the line current I_0 is in phase with applied voltage E_0.

The differences between these resonance frequencies in ordinary circuits are of the order of a fraction of 1 per cent and are trivial except when accurate measurements or extremely critical circuit adjustments are involved. An example of the latter case is the adjustment of a transmitter tank circuit for the highest possible efficiency. Condition 4, which gives zero phase angle and unity power factor for the equivalent impedance of the circuit at resonance, is the most common definition of parallel resonance.

5. Z_0 = *Pure R, and R_C and R_L Not Negligible.*

$$f_r = \frac{1}{2\pi\sqrt{LC}}\sqrt{\frac{L - R_L^2C}{L - R_C^2C}} \tag{38}$$

6. Z_0 = *Pure R, and R_C Negligible.*

$$f_r = \frac{1}{2\pi\sqrt{LC}}\sqrt{1 - \frac{R_L^2C}{L}} = \frac{1}{2\pi\sqrt{LC}}\sqrt{1 - \frac{1}{Q_r^2}} \quad \text{(approx)} \tag{39}$$

where Q_r is the coil Q at resonance. This is the most useful expression for f_r for practical applications.

7. *Approximation When $R_L = R_C$ or When R_C and R_L Are Both Negligible.*

$$f_r = \frac{1}{2\pi\sqrt{LC}} \tag{40}$$

* $|Z_0|$ is the magnitude of the equivalent impedance.

This ignores circuit resistance entirely and is used when approximate results are satisfactory.

8. *Special Case When* $R_L = R_C = \sqrt{L/C}$. The circuit is resonant at all frequencies and $Z_0 = R_L = R_C = \sqrt{L/C}$ at all frequencies. Since L/C is usually of the order of 10^6, Z_0 will be about 1,000 ohms, which limits the practical applications of the circuit.

16. Impedance Relations in Parallel-resonant Circuits. Exact impedance and phase-angle equations are given in Fig. 32*b*. The following are practical approximations.

Impedance at resonance (R_C negligible):

$$Z_r = \frac{X_C^2}{R_L} = \frac{X_L^2}{R_L} = \frac{X_L X_C}{R_L} = \frac{L}{R_L C} \quad \text{ohms (resistive)} \tag{41}$$

Impedance at any frequency, f_1 (R_C negligible):

$$Z_1 = X_C \frac{R_L X_C - j(R_L^2 + X_L^2 - X_L C_C)}{R_L^2 + (X_L - X_C)^2} = |Z_1| \underline{/\phi_1} \tag{42}$$

$$|Z_1| = \frac{X_C \sqrt{R_L^2 + X_L^2}}{\sqrt{R_L^2 + (X_L - X_C)^2}} \tag{43}$$

$$\phi_1 = \tan^{-1}\left(-\frac{R_L^2 + X_L^2 - X_L X_C}{R_L X_C}\right) \tag{44}$$

If $R_L \ll X_L$,

$$|Z_1| = \frac{L}{C} \frac{1}{\sqrt{R_L^2 + (X_L - X_C)^2}} = \frac{L}{C} \frac{1}{\sqrt{R_L^2 + 4\pi^2 L^2 \left(\dfrac{f_1^2 - f_r^2}{f_1}\right)^2}} \tag{45}$$

Subscript$_{(r)}$ denotes values at resonance, and subscript$_{(1)}$ values at any frequency, f_1.

Impedance in terms of Q:

The comments in Sec. 14 relative to variation of R and Q in series-resonant circuits also apply here.

At resonance (R_C negligible, $Q > 25$):

$$Z_r = \frac{Q_r}{\omega_r C} = Q_r \omega_r L = R Q_r^2 \quad \text{ohms} \tag{46}$$

and

$$\frac{Z_r}{\omega_r L} = Q_r \tag{47}$$

where Q_r = coil Q at resonance.

At any frequency, f_1 (R_C negligible, $Q > 25$) for *constant R:*

$$\frac{|Z_1|}{\omega_r L} = \frac{\sqrt{\dfrac{1}{Q_r^2} + n^2}}{n\sqrt{\dfrac{1}{Q_r^2} + n^2 + \dfrac{1}{n^2} - 2}} \tag{48}$$

$$\phi_1 = \tan^{-1}[-nQ_r(n^2 - 1)] \tag{49}$$

where $n = f_1/f_r$.

Figure 38 is a family of resonance curves for $|Z_1|/\omega_r L$ vs. frequency ratio n, plotted for the condition of constant R. Figure 39 is a corresponding set of curves for ϕ_1.
Fig. 38. Parallel-resonance curves.
Fig. 39. Phase angle of parallel LC circuit in terms of n and Q.

For *constant* Q (R_C negligible, $Q > 25$):

$$\frac{|Z_1|}{\omega_r L} = \frac{\sqrt{(1/Q^2) + 1}}{\sqrt{(n^2/Q^2) + n^2 + (1/n^2) - 2}} \tag{50}$$

$$\phi_1 = \tan^{-1}[-Q(n^2 - 1)] \tag{51}$$

where $n = f_1/f_r$.

In all cases, ϕ_1 is positive when f_1 is less than f_r and is negative when f_1 is greater than f_r.

When the circuit Q is 25 or larger, the impedance of a parallel LCR circuit at $f_1 = 0.707 f_r$ and at $f_1 = 1.414 f_r$ is

$$|Z_1| = \frac{1.414}{Q_r}|Z_r| \qquad \text{or} \qquad \frac{|Z_1|}{|Z_r|} = \frac{1.414}{Q_r} \tag{52}$$

This is the basis for one method of measuring the Q of an inductance coil. The coil is connected in parallel with a low-loss variable capacitor, and voltage is applied from a constant-voltage variable-frequency source. The line current (I_r) is measured at resonance frequency and at 70.7 per cent or 141.4 per cent of resonance frequency (I_1), and Q is then determined from the relation

$$Q = 1.414\frac{|I_1|}{|I_r|}$$

17. Line and Circulating Currents in Parallel-resonant Circuits. The true circulating current in a parallel-resonant circuit operating at or very near resonance frequency is the current representing the energy oscillating to and fro between L and C. This is a relatively large current (as compared to line current) and is a component of both the L branch and the C branch currents I_L and I_C (see Fig. 37). A second component of I_L is the current representing the losses in the L branch, which include the I^2R_L loss due to the equivalent ohmic resistance of the branch plus the energy taken from the circuit by any inductively coupled load. A second component of I_C represents ohmic losses in the C branch plus any load that may be coupled to that branch.

In addition, if the applied voltage E_0 is not sinusoidal and of frequency $= f_r$, the harmonic currents through the L and C branches will not be equal because the reactances of the two branches are equal (approximately) only at the resonance frequency f_r. Thus currents produced by components of E_0 whose frequency is less than f_r will flow principally through the L branch, while those whose frequency is greater than f_r will flow principally through the C branch. Hence the total I_L is not actually equal to the total I_C and the difference is the line current, I_0.

In some cases, when the total losses of the LCR circuit are small, it is assumed that the circulating current is $I_L = I_C$. At the same time the line current cannot be ignored but is given by the approximation

$$I_0 = \frac{I_L}{Q} = \frac{I_C}{Q} \tag{53}$$

or, in terms of I_0,

$$I_L = I_C = QI_0 \tag{53a}$$

This approximation is most nearly accurate when the applied voltage is sinusoidal and has frequency f_r and when the circuit Q is high; it is inaccurate under any other conditions.

18. Design of Parallel-resonant Circuits. To design a parallel-resonant circuit, we have to determine values of L, C, R_L, and R_C to satisfy a given set of conditions. Values of $|Z_r|$ at resonance, the resonance frequency, and Q will first have to be determined by analysis of the intended use of the resonant circuit.

In a vacuum-tube oscillator, for example, f_r of the tuned circuit is known, and $|Z_r|$ at resonance is fixed by the permissible plate voltage swing. For Q (which includes the effect of the external load coupled to the tuned circuit, as well as the latter's ohmic resistance) a value of from 12 to 20 represents a good compromise between oscillator efficiency and frequency stability.

Another example of the factors involved in the choice of Q in an application is that of a tuned circuit for an r-f amplifier to pass a modulated carrier. In this case the LC circuit must have sufficient decrement to damp out its own natural oscillations between successive peaks of modulation; otherwise there is an effective decrease in modulation percentage with a corresponding loss of fidelity. If the carrier frequency is f_C and the modulation frequency f_m, the maximum decrement of the modulated carrier wave at 100 per cent modulation is approximately

$$\delta_1 = 2.303 \log_{10}\left(\frac{1}{1 - \pi\frac{f_m}{f_C}}\right) \tag{54}$$

The decrement δ_2 of the tuned circuit should be 10 to 20 times as large as δ_1 for faithful response. Then Q for the tuned circuit is

$$Q = \frac{\pi}{\delta_2} \tag{55}$$

The value of $|Z_r|$ at resonance will depend upon plate-load impedance requirements of the amplifier tube.

In some cases the ratio of volt-amperes circulating in LC to watts dissipated is the basis for the design of an LC circuit; in this case

$$Q = \frac{\text{volt-amp stored}}{\text{watts dissipated}} \tag{56}$$

The effect of any load coupled to a tuned circuit must be taken into account as part of the total effective R of the circuit. If the power taken by the load is W_d watts and I_C is the circulating current in LCR, the total equivalent impedance of the circuit is, approximately,

$$R = R_0 + \frac{W_d}{I_C^2} \quad \text{ohms} \qquad \text{(approx)} \tag{57}$$

where R_0 is the ohmic resistance.

Examples of Design of Parallel-resonant Circuit. Assume that a parallel circuit (Fig. 37) is to be resonant at 5,000 cycles, with an impedance of 4,000 ohms at resonance ($n = 1$) and an impedance of 100 ohms at 3,000 cycles ($n = 0.6$). From Fig. 38, $|Z_1|/\omega_r L = 0.9$ for all values of Q when $n = 0.6$. At resonance $|Z_r|/\omega_r L$ is to be $(4{,}000/100) \times 0.9 = 36$. From the curves it is found that $Q = 36$ gives $|Z_r|/\omega_r L = 36$ at $n = 1$ where $\omega_r = 31{,}416$. Then for $n = 1$,

$$Z_r = 36\omega_r L = 4{,}000 \quad \text{or} \quad L = \frac{4{,}000}{36 \times 31{,}416} = 0.00354 \quad \text{henry}$$

LC for 5,000 cycles $= 10.136 \times 10^{-10}$. Then $C = LC/L = 0.286 \times 10^{-6}$ farad, and $R = \omega_r L/Q = 3.08$ ohms.

As a second example suppose there is to be designed a tuned circuit for an r-f amplifier which requires a plate-load impedance of 10,000 ohms and which is to amplify a 1,000-kc carrier with amplitude modulation up to 5,000 cycles. From Eq. (54),

$$\delta_1 = 2.303 \log_{10} \frac{1}{1 - \pi\frac{5 \times 10^3}{10^6}} = 0.0159$$

$$\delta_2 = 20\,\delta_1 = 0.318$$

$$Q = \frac{\pi}{\delta_2} = 9.85 \doteq \frac{|Z_r|}{\omega_r L} \qquad \text{from Eq. (55)}$$

$$\omega_r L = \frac{|Z_r|}{Q} = \frac{10{,}000}{9.85} = 1{,}015$$

$$L = \frac{\omega_r L}{\omega_r} = \frac{1{,}015}{2\pi f_c} = 162 \qquad \mu\text{h}$$

$$LC \text{ for } 1{,}000 \text{ kc} = 2.53 \times 10^{-10}$$

$$C = \frac{LC}{L} = \frac{2.53 \times 10^{-10}}{162 \times 10^{-6}} = 157 \qquad \mu\mu\text{f}$$

$$R = \frac{\omega_r L}{Q} = \frac{1{,}015}{9.85} = 103 \qquad \text{ohms}$$

This consists of the ohmic resistance of LCR plus the equivalent R of the coupled load, as computed by Eq. (57).

19. Tapped Tank Circuits. In some cases the high impedance of a parallel LCR circuit at resonance is a disadvantage, *e.g.*, at the end of a low-impedance transmission line where the correct termination is about 500 ohms. However, the low impedance can be obtained by tapping the LCR circuit in either the L or C branch as shown in Fig. 40. The result is a coupled circuit, that part of the reactance between B and C being the mutual impedance.
FIG. 40. Tapped tank circuits.

1. *Capacitance Tapped.* In Fig. 40a, the impedance at B-C is

$$|Z_{BC}| = \frac{\sqrt{L^2C_2^2\left(\frac{1}{C_1(C_1 + C_2)}\right)^2 + \frac{R^2LC_2}{C_1(C_1 + C_2)}}}{R} \tag{58}$$

If R is small,

$$|Z_{BC}| = \frac{LC_2}{RC_1(C_1 + C_2)} \tag{58a}$$

and its ratio to the impedance Z_{AC} is

$$\frac{|Z_{BC}|}{|Z_{AC}|} = \frac{C_2^2}{(C_1 + C_2)^2} \tag{59}$$

The resonant frequency is

$$f_r = \frac{1}{2\pi\sqrt{L\frac{C_1C_2}{C_1 + C_2}}} \tag{60}$$

and the impedances Z_{AC} and Z_{BC} are both purely resistive at resonance.

The ratio of C_1 to C_2 for a given ratio between Z_{AC} and Z_{BC} is

$$\frac{C_1}{C_2} = \left(\sqrt{\frac{Z_{AC}}{Z_{BC}}} - 1\right) \tag{61}$$

In terms of the resonant frequency, inductance, and the impedance ratio,

$$C_1 = \frac{1}{4\pi^2 f_r^2 L}\sqrt{\frac{Z_{AC}}{Z_{BC}}} \tag{62}$$

$$C_2 = \frac{1}{4\pi^2 f_r^2 L\left(1 - \sqrt{\frac{Z_{BC}}{Z_{AC}}}\right)} \tag{63}$$

2. *Inductance Tapped.* In Fig. 40*b* the inductance is tapped, and the impedance at *B-C* is (assuming no mutual inductance between L_1 and L_2)

$$|Z_{BC}| = \frac{\sqrt{\left(R_1R_2 - \frac{L_1L_2}{(L_1 - L_2)C_2} + \frac{L_2}{C_2}\right)^2 + \left(\frac{R_2L_1}{\sqrt{(L_1 + L_2)C_2}} + \frac{R_1L_2}{\sqrt{(L_1 + L_2)C_2}} - \frac{R_1\sqrt{(L_1 + L_2)C_2}}{C_2}\right)^2}}{R_1 + R_2} \tag{64}$$

If R_1 and R_2 are small,

$$|Z_{BC}| = \frac{L_2^2}{C_2(R_1 + R_2)(L_1 + L_2)} \tag{64a}$$

and its ratio to the total impedance Z_{AC} is

$$\frac{|Z_{BC}|}{|Z_{AC}|} = \frac{L_2^2}{(L_1 + L_2)^2} \tag{65}$$

The resonant frequency is

$$f_r = \frac{1}{2\pi\sqrt{(L_1 + L_2)C_2}} \tag{66}$$

and the impedances Z_{AC} and Z_{BC} are both resistive at resonance.

The ratio of L_1 to L_2 for a given ratio between Z_{AC} and Z_{BC} is

$$\frac{L_1}{L_2} = \sqrt{\frac{Z_{AC}}{Z_{BC}}} - 1 \tag{67}$$

In terms of the frequency, capacitance, and the impedance ratio,

$$L_1 = \frac{1}{4\pi^2 f_r^2 C_2}\left(1 - \sqrt{\frac{Z_{BC}}{Z_{AC}}}\right) \tag{68}$$

$$L_2 = \frac{1}{4\pi^2 f_r^2 C_2}\sqrt{\frac{Z_{BC}}{Z_{AC}}} \tag{69}$$

20. Resonant Circuits in Tandem. In a network of pure reactances, the number of poles is never different by more than one from the number of zeros (including the zero and pole at each extreme, one at zero and the other at infinite frequency), and the zeros or poles occur alternately with respect to increasing frequency.

Thus when two parallel-resonant circuits are connected in series as in Fig. 41*a*, a new zero, or series resonance, is introduced at some frequency between the two original poles. The new resonance is at

$$f = \frac{1}{2\pi}\sqrt{\frac{L_1 + L_2}{L_1L_2(C_1 + C_2)}} \tag{70}$$

Similarly, with two series-resonant circuits in parallel as in Fig. 41*b*, a pole appears between their zeros at

$$f = \frac{1}{2\pi}\sqrt{\frac{C_1 + C_2}{C_1C_2(L_1 + L_2)}} \tag{70a}$$

Other cases of multiple resonance involving resonant circuits and reactances in tandem are listed among the inverse two-terminal networks of Sec. 36.

Multiple resonance imposes practical limits on the way in which resonant circuits may be combined, since unwanted resonances may occur unless the branches are isolated from each other. It prevents, for example, the use of more than one parallel LC peaking circuit in the plate circuit of a single amplifier stage. In this case, the necessary isolation may be achieved by placing the other peaking circuits in different stages. Inserting resistance between resonant branches often solves the isolation problem in passive networks, but at the cost of additional losses.
FIG. 41. Resonant circuits in tandem.

There are, of course, many applications where multiple resonance serves a useful purpose, notably in the design of impedance branches for four-terminal wave filters and corrective networks.

COUPLED CIRCUITS

21. Coupling. Two circuits are coupled if they have a common impedance so situated that it causes the current flowing in one circuit to influence the current in the other. The common impedance may be resistance, capacitance, inductance, mutual inductance, or any combination of these. In the general case where it contains both resistance and reactance, the analysis is complicated.[1]

22. Coefficient of Coupling. The extent of coupling between two circuits is called the *coefficient of coupling* and is

$$K = \frac{X_m}{\sqrt{X_1X_2}} \tag{71}$$

where X_m is any one component of the mutual impedance (ωL_m, $1/\omega C_m$, or ωM in ohms) and X_1 and X_2 are the total impedance components of the same kind in the respective circuits, including the mutual impedance. K varies in value between 0 and 1; if it is nearly 1, the coupling is *close* or *tight;* if it is near 0 ($K = 0.1$ or less), the coupling is *loose.*

23. Coupling Coefficients for R-f Circuits. Values of K for four types of coupling most used in r-f circuits are given in Fig. 42.

24. Mutual Inductance Coupling at Low Frequencies. In Fig. 43 circuit I is coupled to circuit II by the transformer (mutual inductance) T. The primary and secondary windings, X_p and X_s, are assembled on a closed iron core. At low frequencies, including audio and commercial power frequencies, the magnetic coupling is almost perfect, which results in a large value of M and makes K nearly equal to 1. Also X_p and X_s have sufficient inductance so that $X_p \gg Z_1$ and $X_s \gg Z_2$.

Under these conditions, the following approximate relations hold:

Impedance looking into primary:

$$Z_0 = \frac{X_p}{X_s} Z_2 = \left(\frac{N_p}{N_s}\right)^2 Z_2$$

[1] For discussions of this case, see G. W. Pierce, "Electric Oscillations and Electric Waves," McGraw-Hill, 1920, and C. B. Aiken, Two-mesh Tuned Coupled Filters, *Proc. IRE*, February, 1937, p. 230.

where N_p and N_s are number of turns in primary and secondary windings, respectively.

Current ratio:

$$\frac{I_1}{I_2} = \frac{N_s}{N_p} \qquad I_2 = \frac{N_p}{N_s} I_1 \qquad I_1 = \frac{N_s}{N_p} I_2$$

Voltage ratio:

$$\frac{E_1}{E_2} = \frac{N_p}{N_s} \qquad E_1 = \frac{N_p}{N_s} E_2 \qquad E_2 = \frac{N_s}{N_p} E_1$$

Volt-amperes:

$$E_1 I_1 = E_2 I_2 + \text{transformer losses}$$

Impedance ratio:

$$\frac{Z_0}{Z_2} = \left(\frac{N_p}{N_s}\right)^2 \qquad \frac{Z_2}{Z_0} = \left(\frac{N_s}{N_p}\right)^2$$

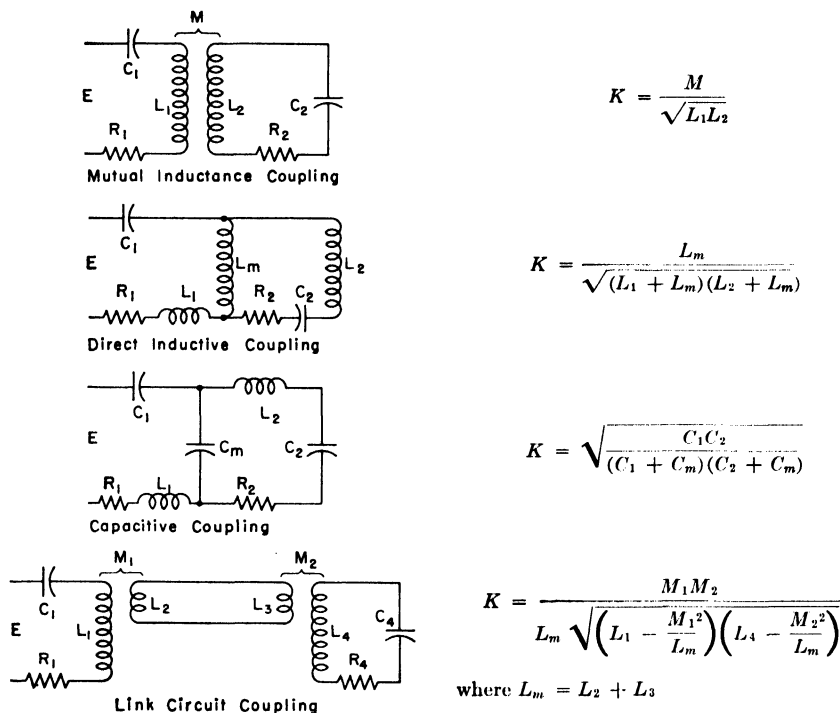
These simple relations are not quite exact for any actual transformer because of core losses, flux leakage, and resistance and distributed capacitance of windings. Also,


FIG. 42. Commonly used types of coupled circuits and their coupling coefficients.

since these imperfections vary with frequency, the various ratios likewise change with frequency. A well-designed transformer may give results approaching 90 to 95 per cent of the values given.

To minimize the effects of these imperfections, transformer designs must take into account not only the ratios but also the actual values of primary and secondary currents and impedances. For this reason, a-f transformers are rated in terms of the actual impedances between which they are designed to operate, and the frequency

range over which they will give satisfactory performance. Their performance outside these ratings is likely to be deficient. Thus, an a-f transformer designed to match one impedance of 500 ohms to another of 50 ohms (Z ratio of 10:1) probably would not give satisfactory results if used between impedances of 50,000 and 5,000 ohms, even though the impedance ratio is the same.

25. Mutual Inductance Coupling at Radio Frequencies. Excessive core losses, high resistance of windings, and large distributed capacitance bar the use of a-f types of iron-cored transformers in r-f circuits. Without iron cores, only small values of coupling between primary and secondary can be realized. Open cores of powdered iron are frequently used in r-f transformers, but their effect is principally to increase the circuit Q with little effect on the coupling. However, the range of frequencies that an r-f transformer is required to pass efficiently is usually small in comparison with the center frequency. The side bands of an a-f modulated signal, for instance, occupy a frequency band whose width is only 2 or 3 per cent of the carrier frequency. (This is not true for all types of radio signals, however. A television signal may require a band width of 10 to 15 per cent of the carrier frequency. In this case, simple transformer circuits are not suitable coupling devices.)

FIG. 43. Transformer coupling of low-frequency circuits.

When the band width is a small percentage of the center frequency, the limited values of K in an r-f transformer can be compensated by resonating the primary and secondary circuits. The transfer of energy in such an arrangement will vary with frequency, but this can be made reasonably constant over a narrow band that is still sufficiently wide to accommodate side bands.

26. Practical Relations in Transformer-coupled R-f Circuits. A practical application of a tuned coupled r-f circuit is shown in Fig. 44, which represents an i-f transformer used to couple the output of a pentode tube to the grid of the following tube.

FIG. 44. R-f amplifier stage with tuned coupled circuits.

The same circuit and the formulas pertaining to it apply equally well to t-r-f coils with untuned primaries if C_p is eliminated from both circuit and equations.

For practical purposes, the effectiveness of the coupled circuit of Fig. 44 is determined by its gain and its selectivity. These quantities are dependent not only upon the L, R, and C of the coupling circuits themselves, but also upon the effective input and output impedances of the two tubes, which shunt the primary and secondary and alter their resistance and capacitance.

The circuit of Fig. 44 is very nearly equivalent to that of Fig. 45 if

$$C_1 = C_p + C_o \qquad L_1 = L_p \qquad R_1 = \frac{1}{\omega^2 C_1^2 r_p} + r_p$$

$$C_2 = C_s + C_i \qquad L_2 = L_s \qquad R_2 = \frac{1}{\omega^2 C_2^2 R_i} + R_i$$

where C_o = output capacitance of tubes
C_i = input capacitance of tubes
r_p = tube plate resistance
R_i = tube input ohmic resistance
L_1 and L_2 = self-inductances of primary and secondary coils, each determined with the opposite circuit removed or uncoupled

For pentode tubes, the circuit input voltage is approximately
FIG. 45. Coupling-circuit equivalent of Fig. 44.

$$E_0 = \frac{G_m}{\omega C_2} \times E_i \qquad (72)$$

where E_i = input voltage to grid of first tube. The equivalent voltage E_0 may be considered as coming from a source having zero internal impedance.

For triodes, the equivalent voltage is approximately

$$E_0 = \mu \times E_i \qquad (73)$$

but in this case it must be considered as coming from a source whose internal impedance is equal to r_p, the plate resistance of the first tube. E_g is the actual input voltage to the grid of the second tube.

27. Band-pass Characteristics of Coupled Circuits. If the primary and secondary circuits are individually tuned to the same frequency f_0 so that $L_1C_1 = L_2C_2$ (L_1 not necessarily equal to L_2, nor C_1 to C_2), the secondary current I_2 varies with frequency according to one of the resonance curves of Fig. 46. Since E_g applied to the grid of the following tube is nearly proportional to I_2 for narrow bands, these curves also represent output voltage and, therefore, the gain vs. frequency characteristic of the amplifier stage.

FIG. 46. Variation of secondary current and gain with frequency and with degree of coupling.

The *shape* of the response curve depends upon the ratio of X_m^2 to $(R_1^2 + R_2^2)/2$,* while the *peak gain* depends upon the ratio of X_m^2 to R_1R_2. With mutual inductance coupling, $X_m = \omega M$.

1. *Peak Values of Secondary Current and Voltage vs. Coupling.*

CRITICAL COUPLING: When $X_m^2 = R_1R_2$, the coupling is called *critical*, and the curve has its maximum at f_0, as shown by curve 2, Fig. 46. Critical coupling also gives the maximum possible peak value, and this is

$$I_{2\,\max} = \frac{E_0}{2\sqrt{R_1R_2}} \quad \text{(approx)} \qquad (74)$$

or

$$E_{g\,\max} = \frac{E_0}{2\omega_0C_2\sqrt{R_1R_2}} \quad \text{(approx)} \qquad (74a)$$

where $\omega_0 = 2\pi f_0 = 1/\sqrt{L_1C_1} = 1/\sqrt{L_2C_2}$, and other quantities refer to the equivalent circuit of Fig. 45.

* This was pointed out by Aiken, *loc. cit.*

In terms of K and Q, the coupling is critical when $K = 1/\sqrt{Q_1Q_2}$, where Q_1 and Q_2 are the respective Q's of the primary and secondary circuits. Practically, these are approximately the Q's of the primary and secondary coils. If $Q_1 = Q_2 = Q, K = 1/Q$ for critical coupling.

UNDERCOUPLING: When $X_m^2 < R_1R_2$, the circuits are *undercoupled.* In this case, the curve has a lower maximum than for the case of critical coupling, as shown by curve 1, Fig. 46.

OVERCOUPLING: When $X_m^2 > R_1R_2$, the circuits are *overcoupled.* This may produce either a single or double peak, the latter case being shown by curve 3. In either case, the peak or peaks are equal to the maximum for critical coupling if $R_1 = R_2$, and slightly less if $R_1 \neq R_2$.

2. *Frequency Characteristic and Shape of Curves.*

SINGLE PEAK CURVE: When $X_m^2 \leqq (R_1^2 + R_2^2)/2$, the curve has a single peak (curves 1 and 2, Fig. 46) and has approximately the same shape as the resonance curve of a parallel LCR circuit whose $Q = \sqrt{Q_1Q_2}$.

DOUBLE PEAK CURVE: When $X_m^2 > (R_1^2 + R_2^2)/2$, the curve has a double peak (curve 3). If, in addition, $R_1 = R_2 = R$, the value of coupling for transition from the condition of single peak to double peak is the same as the value for critical coupling, and $X_m = R$. Furthermore, the peaks have maximum possible value.

3. *Selectivity and Gain.* Increasing coupling increases gain, up to the point of critical coupling, and reduces selectivity and, in practice, the best value of X_m is a compromise beween gain and selectivity. For example, in i-f transformers for a-f modulated signals, it is common practice to adjust coupling to about 80 per cent of critical.

In i-f circuits where high fidelity of response is of major importance, overcoupling is frequently used to broaden the nose of the curve by double peaking. This passes efficiently the upper side bands due to higher a-f modulating frequencies. Such a curve is shown in curve 3 of Fig. 46 and is reproduced in Fig. 47 with dimensions added for reference in Sec. 28.
FIG. 47. Band-pass characteristic of overcoupled circuit.

28. Equations for Band Width and Gain. Although it is ordinarily easier to measure the response curve of a coupled circuit than it is to measure R_1 and R_2 and calculate the curve, relations between circuit parameters and gain and response are useful for design and analysis. The following relations give close approximations to exact values for the circuits of Figs. 44 and 45 and are based partly on Aiken's[1] results. The principal assumptions are that the band width is negligible compared to f_0, that R_1 and R_2 are constant throughout the band width, and that E_g is proportional to I_2.

Symbols used in gain and band-width equations:

E_i = input voltage to first tube grid (Fig. 44)

E_g = input voltage to second tube grid

$$\omega_0 = \frac{1}{\sqrt{L_1C_1}} = \frac{1}{\sqrt{L_2C_2}}, \text{ both circuits tuned to } f_0 = \frac{\omega_0}{2\pi}$$

$$K = \frac{M}{\sqrt{L_1L_2}}$$

[1] *Ibid.*

$$Q_1 = \frac{\omega_0 L_1}{R_1}$$

$$Q_2 = \frac{\omega_0 L_2}{R_2}$$

G_m = tube transconductance

Gain at center frequency for any value of coupling is proportional to dimension c at f_0 of Fig. 47 for either single or double peak curves and is

$$\frac{E_g}{E_i} = \frac{G_m M}{\omega_0 C_1 C_2 (R_1 R_2 + \omega_0^2 M^2)} = \frac{G_m \omega_0 K \sqrt{L_1 L_2}}{\dfrac{1}{Q_1 Q_2} + K^2} \tag{75}$$

If both circuits are identical and $R_1 = R_2 = R$, $Q_1 = Q_2 = Q$, and $L_1 = L_2 = L$, the gain is

$$\frac{E_g}{E_i} = \frac{G_m M}{\omega_0 C_1 C_2 (R^2 + \omega_0^2 M^2)} = \frac{G_m \omega_0 K L}{\dfrac{1}{Q_2} + K^2} \tag{76}$$

Maximum possible gain at center frequency is proportional to dimension p at f_0 and occurs when coupling is critical ($\omega_0 M = R_1 R_2$ or $K = 1/\sqrt{Q_1 Q_2}$) for either single or double peak curves and is

$$\frac{E_g}{E_i}\max = \frac{G_m \omega_0^2 L_1 L_2}{2\sqrt{R_1 R_2}} = \frac{G_m Q_1 Q_2 \sqrt{R_1 R_2}}{2} \tag{77}$$

If both circuits are identical and $R_1 = R_2 = R$, $Q_1 = Q_2 = Q$, and $L_1 = L_2 = L$, the gain is

$$\frac{E_g}{E_i}\max = \frac{G_m \omega_0^2 L^2}{2R} = \frac{G_m Q^2 R}{2} = \frac{G_m Q \omega_0 L}{2} \tag{78}$$

Gain at peaks of double peak curve (when $2\omega_0^2 M^2 > R_1^2 + R_2^2$) is the dimension p at f_1 and f_2 of Fig. 47 and is

$$\frac{E_g}{E_i} = \frac{2G_m M}{\omega_0 C_1 C_2 \sqrt{4\omega_0^2 M^2 (R_1 + R_2)^2 - (R_1^2 - R_2^2)}} \tag{79}$$

If $R_1 = R_2 = R$, the gain is

$$\frac{E_g}{E_i} = \frac{G_m}{2\omega_0^2 C_1 C_2 R} = \frac{Q_1 Q_2 R G_m}{2} = \frac{Q_1 \omega_0 L_1 G_m}{2} \tag{80}$$

Transition from single to double peak occurs when

$$f_0 = \frac{1}{2\pi M}\sqrt{\frac{R_1^2 + R_2^2}{2}} \quad \text{or} \quad M = \frac{1}{\omega_0}\sqrt{\frac{R_1^2 + R_2^2}{2}} \tag{81}$$

If $R_1 = R_2 = R$, transition occurs when

$$f_0 = \frac{R}{2\pi M} \quad \text{or} \quad M = \frac{R}{\omega_0} \tag{82}$$

Band width, peak to peak, **when $L_1 = L_2 = L$ is the dimension $(BW)_p$ in Fig. 47 and is**

$$(BW)_p = \frac{0.1592}{L}\sqrt{\omega_0^2M^2 - \frac{R_1^2 + R_2^2}{2}} = f_0\sqrt{K^2 - \frac{1}{2}\left(\frac{1}{Q_1^2} + \frac{1}{Q_2^2}\right)} \tag{83}$$

If $R_1 = R_2 = R$,

$$(BW)_p = \frac{0.1592}{L}\sqrt{\omega_0^2M^2 - R^2} = f_0\sqrt{K^2 - \frac{1}{4Q^2}} \tag{84}$$

If Q_1 and Q_2 are both large,

$$(BW)_p = Kf_0 \qquad \text{(approx)} \tag{85}$$

Band width between points on curve where gain equals gain at center frequency is $(BW)_c$ in Fig. 47 and is

$$(BW)_c = \sqrt{2}\,(BW)_p = \frac{0.225}{L}\sqrt{\omega_0^2M^2 - \frac{R_1^2 + R_2^2}{2}} \tag{86}$$

$$= \sqrt{2}f_0\sqrt{K^2 - \frac{1}{2}\left(\frac{1}{Q_1^2} + \frac{1}{Q_2^2}\right)} \tag{87}$$

If $R_1 = R_2 = R$,

$$(BW)_c = \frac{0.225}{L}\sqrt{\omega_0^2M^2 - R^2} = \sqrt{2}f_0\sqrt{K^2 - \frac{1}{Q_2}} \tag{88}$$

If Q_1 and Q_2 are both large,

$$(BW)_c = \sqrt{2}\,Kf_0 \qquad \text{(approx)} \tag{89}$$

Band width at point where gain is n db down from center gain of double peak curve when $L_1 = L_2 = L$ is $(BW)_d$ in Fig. 47:

$$(BW)_d = \frac{0.1125\sqrt{2\omega_0^2M^2 - R_1^2 - R_2^2 + \sqrt{(2\omega_0^2M^2 - R_1^2 - R_2^2)^2 + 4D(R_1R_2 + \omega_0^2M^2)^2}}}{L} \tag{90}$$

where D is a function of n to be read from Fig. 48. Equation (90) is approximate and is not accurate for points more than about 10 db down from center gain.
FIG. 48. Values of D vs. n.

If $R_1 = R_2 = R$,

$$(\text{BW})_d = \frac{0.1592\sqrt{\omega_0^2M^2 - R^2 + \sqrt{(\omega_0^2M^2 - R^2)^2 + D(R^2 + \omega_0^2M^2)^2}}}{L} \tag{91}$$

Coupling for band width of W cycles at n db down from center gain of double peak curve when $L_1 = L_2 = L$ is

$$\omega_0 M = 2.507\sqrt{\frac{LW}{D}\sqrt{39.48L^2W^2(2D+1) + D(R_1+R_2)^2} - \frac{39.48L^2W^2}{D} - R_1R_2} \tag{92}$$

where D is a function of n to be read from Fig. 48. W is identical with $(\text{BW})_d$ in other equations. Equation (92) is approximate and is not accurate for n larger than about 10.

SOME SPECIAL APPLICATIONS OF *LCR* CIRCUITS

29. Band-pass R-f Circuits. If two identical tuned circuits are capacitively or inductively coupled (Fig. 49), the circuit acts as a band-pass filter with a band width approximately

$$f_s = f_1 - f_2 = \frac{\sqrt{X_m^2 - R^2}}{2\pi L} \tag{93}$$

The band width varies with the tuning, increasing with the frequency in the inductive case, and decreasing with the frequency in the capacitive case (Fig. 49). These
FIG. 49. Coupled circuits as band-pass filters.

opposing effects may be combined in the manner shown in Fig. 49, so that the band width is maintained substantially constant while the circuits are tuned over a wide range of frequency by adjustment of C_1 and C_2.

Uehling[1] has shown that this condition obtains when

$$X_{m_n} = \pm\sqrt{R_n^2 + 4\pi^2L^2f_s^2} \tag{94}$$

where R_n is the resistance and L the total inductance of each branch and f_s is the band width. With X_m computed for the two boundary frequencies f_a and f_b of the tuning range, the values of M and C_m required are given by

$$M = \frac{X_{m_b}f_b - X_{m_a}f_a}{2\pi(f_a^2 - f_b^2)} \tag{95}$$

$$C_m = \frac{f_a^2 - f_b^2}{2\pi f_a f_b(X_{m_a}f_b - X_{m_b}f_a)} \tag{96}$$

[1] *Electronics*, September, 1930, p. 279.

Representative values of M and C_m for $f_a = 1{,}500$ kc, $f_b = 550$ kc, $R_a = 30$ ohms, $R_b = 10$ ohms, $L = 200 \times 10^{-6}$ henry, and $f_s = 10$ kc, which are typical constants of broadcast circuits, are

$$M = 3.2 \times 10^{-6} \quad \text{henry} \quad \text{and} \quad C_m = 0.06 \quad \mu\text{f}$$

The inductive coupling M must be negative so that its effect will be additive to that of C_m. This may be obtained by winding the coils M (Fig. 49) of two wires side by side and by connecting the "start" ends of the coils to C_1 and C_2 and the "finish" ends to C_m.

30. Decoupling Filters. When the plate current for several tubes of a high-gain amplifier is obtained from a single source, the internal resistance of the source is common to all the plate circuits and is likely to act as a coupling between stages. Similar couplings may exist through a bleeder circuit when screen voltage for two or more tubes is taken from a common tap or through a bias resistor common to the control-grid circuits of several tubes. To reduce such stray couplings to negligible amounts, decoupling filters are generally inserted in the circuits of each tube and separate bias resistors are used.

FIG. 50. RC filter usage to isolate power-supply system from alternating currents.

A typical application of decoupling filters is shown in Fig. 50, the filter elements being indicated by heavy lines. Capacitors C furnish low-impedance paths back to the cathodes for the signal currents flowing in the grid, screen-grid, and plate circuits, while the high-impedance resistors R and chokes in the leads to the voltage divider prevent any appreciable flow of signal currents in that direction. The choice of values for these resistors and chokes depends principally upon the currents in the leads and the permissible d-c voltage drop in each filter. The impedance of each by-pass capacitor should be not more than 10 per cent of that of the associated resistor or choke, at any frequency for which the amplifier is designed to operate. On the other

FIG. 51. CR circuit for obtaining out-of-phase voltages.
FIG. 52. LC circuit for obtaining out-of-phase voltages.

hand, the value of C should not be so large in any filter that "blocking" or motor-boating occurs due to too high a time constant.

The value of each cathode resistor, when separate biasing resistors are used, is equal to the bias required, divided by the total cathode d.c. of that tube. The screen-grid filter resistors serve as voltage-dropping resistors as well as filters, and their values are determined by the IR drops required for correct screen voltages.

31. Circuits for Obtaining Out-of-phase Voltages and Currents. Two circuits producing voltages 90 or 180 deg out of phase are shown in Figs. 51 and 52 with their vector diagrams. These are often useful in circuit designs and oscillograph measure-

ments. To maintain these phase relations, high-impedance circuits only should be connected across e_1 and e_2.

A circuit for obtaining currents 90 deg out of phase with each other is shown in Fig. 53.
FIG. 53. Circuit for obtaining currents out of phase by 90 deg.

To utilize these currents, nonreactive loads R_L and R_C are introduced, with values such that $R_L R_C = L/C$ and $R_L = R_C$.

32. Frequency Discriminator Circuit. The frequency discriminator circuit shown in Fig. 54 is applied in a.f.c., f-m detection, frequency-drift indicators, etc. L_1C_1 and L_2C_2 are tuned to the same frequency and doubly coupled: (1) directly at B and (2) inductively by M. After rectification, a bias E is obtained which, between limits C and D, is proportional to the difference between the frequency of the input voltage and the resonance frequency of LC. The time constant of R_0C_0 should be much less than the period of one cycle of the *frequency variation* in the input voltage.
FIG. 54. Frequency discriminator and characteristic.

33. Compensation in Resistance-coupled Amplifier. In a conventional resistance-coupled amplifier (Fig. 55) the amplification falls off at low frequencies because of increasing impedance of C_c and at high frequencies because of the shunting effect of stray capacitance C_s. In wide-band amplifiers, the compensating impedances L and R_1C_1 are added. For approximately constant gain between frequency limits f_1 (low) and f_2 (high),

$$\left.\begin{aligned} R_L &= \frac{1}{2\pi f_2 C_s} \qquad & L &= \frac{R_L}{4\pi f_2} \\ C_1 &= \frac{1}{2\pi f_1 R_L} \qquad & R_1 &= 2R_L \end{aligned}\right\} \tag{97}$$
FIG. 55. Compensated resistance-coupled amplifier.

This type of compensation also tends to correct for phase shift near the limits f_1 and f_2.

NETWORKS

34. Types of Networks. A network is any combination of L, C, R, or M impedance elements having two or more terminals for connection to an external circuit. The eventual function of a network is to serve as part or all of a path joining a load to a source, but often the network is considered alone and the remainder of the circuit, including source and load, is merely implicit. If the network contains reactance, its effect on load current will usually vary with frequency; this is expressed quantitatively as the *response* or *characteristic* of the network, usually in the form of a curve or equation.

When the purpose is primarily to convey energy from source to load, the network is a *transmission line.* In this case the impedances are ordinarily distributed *LCRs* whose existence and values are more or less incidental to other factors, but these impedances may, nevertheless, play important roles in the response of the transmission line.

When the principal object is to control or alter the response of a system, the network is a *corrective* device, with deliberately planned impedances. At low frequencies, the impedances are usually lumped because relatively large *LCR* values are required, but at high frequencies they may consist of resonant sections of transmission line.

Depending upon the geometric arrangement of their elements, the most used networks are ladder, bridged-T, or lattice types. The basic sections of these networks
FIG. 56. Basic types of networks.

are shown in Fig. 56. Full series impedance of a ladder network is represented by Z_1, and full shunt arms by Z_2. In a single section removed from a ladder structure, these are halved or doubled as shown in Fig. 56*b* and *c*, so that connection with adjacent sections maintains the values Z_1 and Z_2.

It should be noted that current reaches the load through only one path in a ladder network, while in the bridged-T and lattice types there are two paths from input to output.

35. Poles and Zeros of Impedance. The zero impedance of a network or impedance branch at resonance is called a *zero,* and the infinite impedance at antiresonance frequency is called a *pole.* These expressions are frequently used in describing the characteristics of wave filters and equalizers, where the distribution of zeros and poles in the frequency spectrum is the factor that determines the frequency response of the structure.

Dissipative structures can have poles and zeros only at zero or infinite frequency. Absolute poles and zeros at all other frequencies occur only with pure reactance

networks. However, the terms are often applied when only incidental dissipation exists, as is the usual case in physical networks.

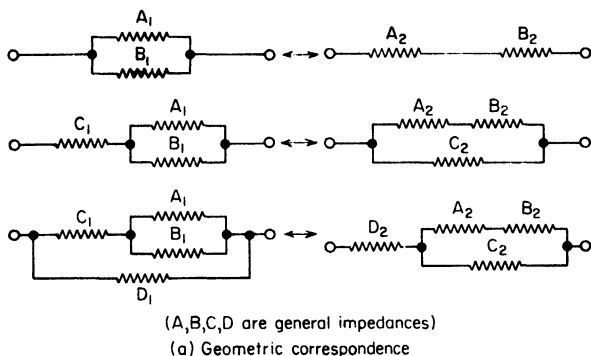
For locating poles and zeros in the frequency spectrum, ω ($= 2\pi f$), sometimes called the radian frequency, is generally used in place of frequency itself, to eliminate the constant repetition of the 2π factor.


FIG. 57. Relations between two-terminal networks mutually inverse with respect to R_0^2.

36. Inverse Two-terminal Networks. Two networks whose impedance product is a constant are inverse with respect to the constant. That is, $Z_{11}Z_{21} = R_0^2$, where Z_{11} and Z_{21} are the network impedances and R_0^2 is the constant. Inverse two-terminal networks have direct application as the series and shunt branches of four-terminal constant-resistance structures. It should be noted that some networks (more complex than any considered here) do not have physically realizable inverse networks.

Definite relationships exist between each impedance element in a network and the corresponding element in the inverse network, with respect to geometrical arrange-

ment or method of connection to other elements, type of element (L, C, or R), and quantitative values. Geometrically, the inverse of a series element is one connected in parallel, and vice versa, as illustrated by Fig. 57*a*. An R in one network is represented by an R, usually of different value, in the inverse structure; an L in one corresponds to C in the inverse, and a C to an L, as shown by Fig. 57*b*. Quantitative relations between elements are also shown in the latter figure, and these may be summarized as

$$Z_{11}Z_{21} = R_{11}R_{21} = \frac{L_{11}}{C_{21}} = \frac{L_{12}}{C_{22}} = \frac{L_{21}}{C_{11}} = \frac{L_{22}}{C_{12}} = R_0^2 \tag{98}$$

In the conventional system of subscript notation used with inverse networks and impedances, the first integer represents the branch of the network to which an element
FIG. 58. Two-terminal networks mutually inverse with respect to R_0^2.

belongs, and the second integer designates a particular element in the branch. Thus, L_{12} denotes element number 2 in branch 1, and C_{22} the corresponding inverse element in branch 2.

At each frequency where branch 1 has a pole, its inverse branch 2 will have a zero, and vice versa.

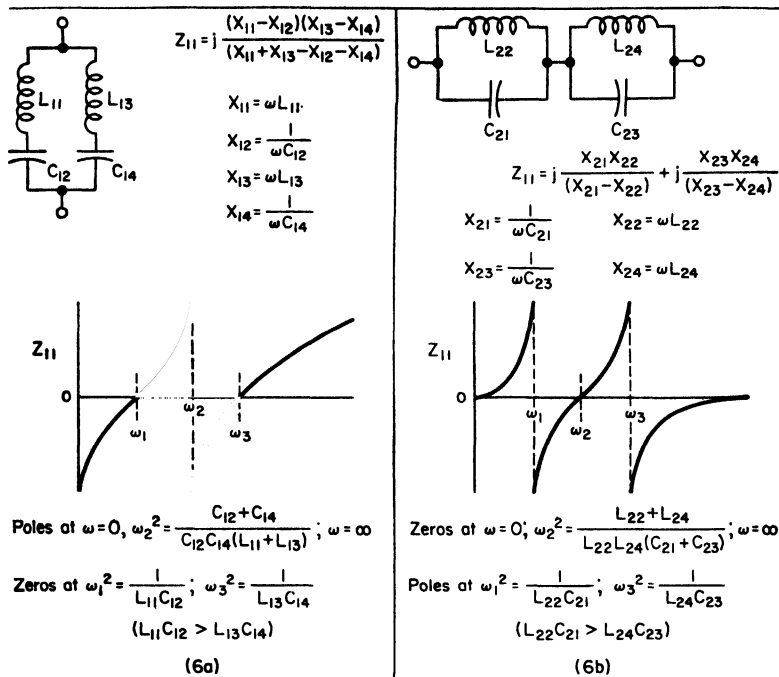
A useful practical property of inverse networks is the fact that any two-terminal network inserted in series between two terminating resistances R_1 and R_2 such that $R_1R_2 = R_0^2$ produces exactly the same insertion loss as does its inverse with respect to R_0^2, when the latter is shunted across the circuit. Use is made of this principle in the design of simple equalizers.

Mutually inverse networks of two-, three-, and four-element types, with their respective equations and curves, are shown by Fig. 58. Actually, these are not all unique networks, since, for example, networks 3a and 4b are potentially equivalent as evidenced by the similarity of their impedance curves. Similar conditions apply

FIG. 58. Two-terminal networks mutually inverse with respect to R_0^2. (*Continued.*)

to 3b and 4a, 5a and 6a, and to 5b and 6b. Thus, only two impedance characteristics are obtainable with any possible combination of three reactance elements in a two-terminal network, and the two corresponding networks are inverse. The same situation exists with respect to four-element networks. This limits the types of response characteristics that may be achieved by employing such two-terminal networks as series and shunt branches in equalizers and wave filters.
FIG. 58. Two-terminal networks mutually inverse with respect to R_0^2. (*Continued.*)

37. Lattice Networks. A symmetrical balanced lattice is shown in Fig. 59. To simplify drawing, the abbreviated form *b* is customarily used, where the dashed lines indicate series and cross impedances identical, respectively, to those explicitly shown. In the balanced lattice section, the total series impedance Z_{11} is equally divided between the two series branches as $\frac{1}{2}Z_{11}$, and each cross impedance Z_{21} is doubled to present mid-shunt termination. Impedances Z_{11} and Z_{21} represent any combinations of *L*, *C*, and *R*, although in most practical cases they are mutually inverse impedances.

A lattice structure is more general than a bridged-T or ladder network, since it is physically realizable for some propagation characteristics for which no realizable bridged T or ladder exists. A physically realizable structure is one that can be built of real *L*s, *C*s, and *R*s (and mutual inductances in some cases), excluding all negative impedance values.


$$Z_{11}Z_{21} = \frac{L_{11}}{C_{21}} = \frac{L_{13}}{C_{23}} = \frac{L_{22}}{C_{12}} = \frac{L_{24}}{C_{14}} = R_0^2$$

FIG. 58. Two-terminal networks mutually inverse with respect to R_0^2. (*Continued.*)

The subscript notation used here for the lattice is the same as the system described for inverse networks in Sec. 36.

Practically, a lattice network has several disadvantages: (1) it usually requires more components than a bridged T or ladder; (2) it is more critical with respect to exact values of the elements and their adjustment; (3) it has no completely unbalanced form allowing one side to be grounded at both terminals.
FIG. 59. Basic lattice section.

Offsetting these disadvantages is the fact that a lattice may be physically realizable for a desired attenuation or phase characteristic when other structures are not. Where it is necessary to use a lattice in an unbalanced circuit, transformers may be used for isolation if suitable ones are available.

38. Transformation of Lattice to Bridged T. Bridged-T equivalent networks may be derived from some lattices, although it is not possible in the case of every lattice. The bridged T has the advantage of requiring fewer components, and also may be used in its unbalanced form in circuits where a lattice would require isolation transformers. A lattice and one form of potentially equivalent bridged T are shown in Fig. 60*a* and *b*.

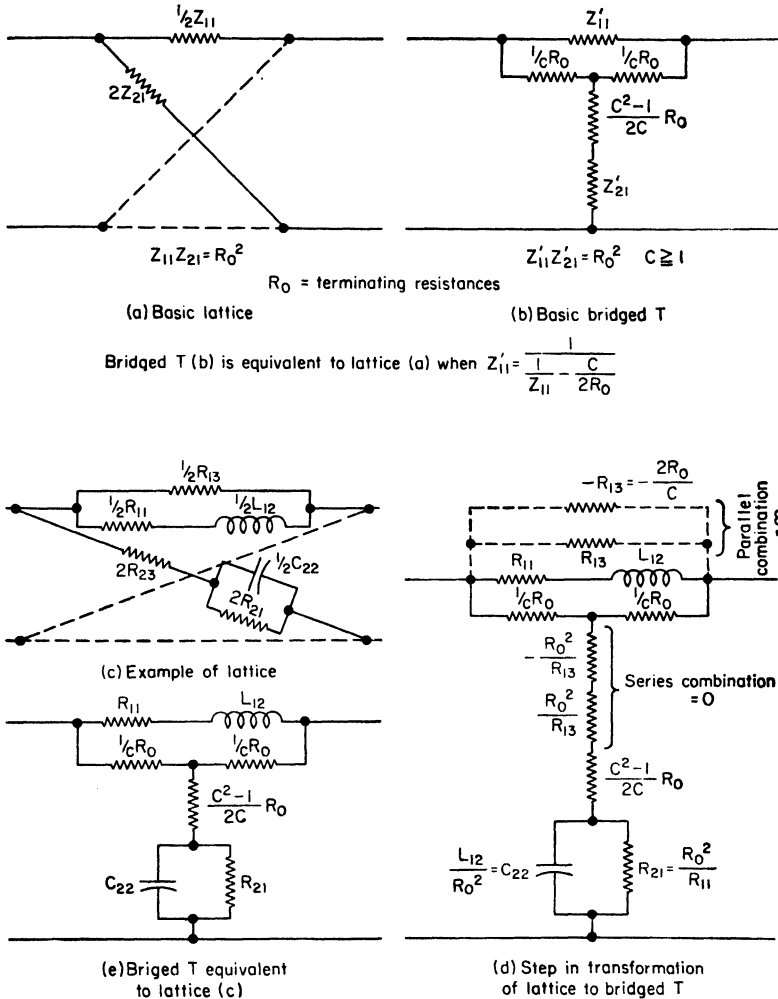
A method of lattice-to-bridged-T conversion described by Zobel[1] yields a physical bridged T when the lattice series branch Z_{11} includes a totally shunting resistance such as $\frac{1}{2}R_{13}$ in Fig. 60c. In this method, a hypothetical negative resistance $-2R_0/c$ is paralleled across the Z_{11} branch and made numerically equal to R_{11} as in Fig. 60d. Because the bridged T is unbalanced, the full value of R_{13} is used, instead of its half


FIG. 60. Bridged T equivalent to lattice equalizer.

value as in the case of the lattice. The actual resistance R_{13} combined with the theoretical negative resistance $-2R_0/c$ is equivalent to infinite resistance; so both may be omitted. The value of c required to achieve this is $c = 2R_0/R_{13}$.

In the shunt branch of the bridged T, the inverse impedances of $-2R_0/c$ and R_{13}—namely, $-R_0^2/R_{13}$ and R_0^2/R_{13}—are in series, and these also effectively cancel

[1] Zobel, Otto J., Distortion Correction in Electrical Circuits with Constant Resistance Recurrent Networks, *Bell System Tech. J.*, **7** (3), 438, July, 1928.

each other. Thus they too can be omitted. Additional real resistances, $(1/c)R_0$ in the series branch and $[(c^2 - 1)/2c]R_0$ in the shunt branch, complete the bridged T as shown in Fig. 60*e*.

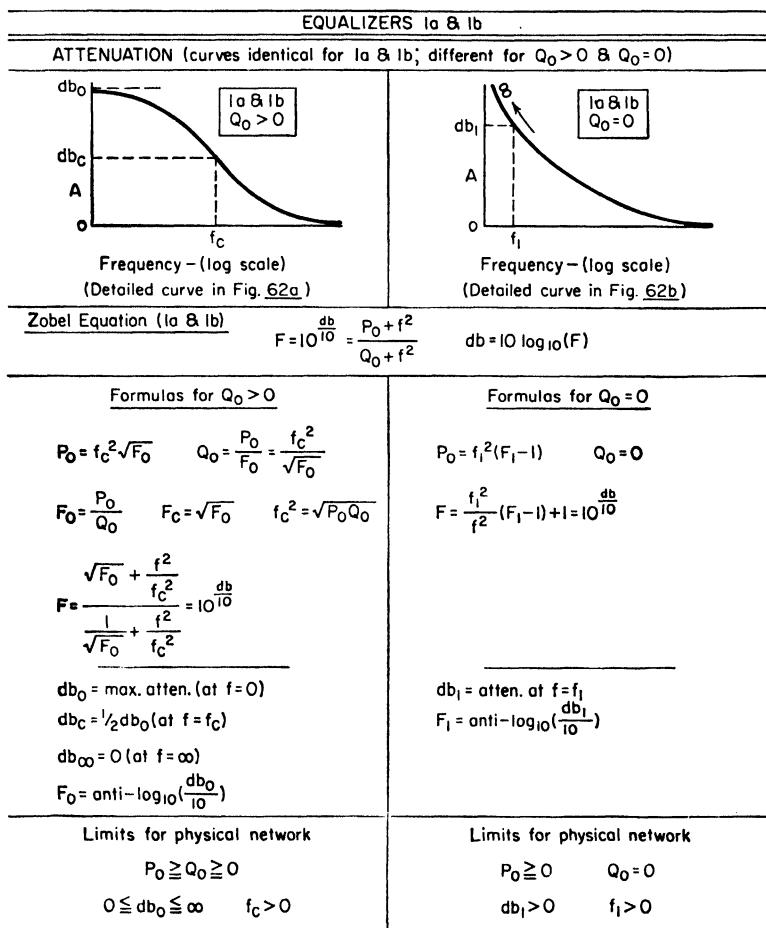
Of the lattice equalizers considered in Sec. 41, the types 1b, 2a, and 3a have the requisite shunt resistances in their series branches and therefore are convertible to bridged Ts by this method. The appropriate values for c in each of these types are given in the equalizer-design data.


FIG. 61*a*. Equalizers.

Other methods exist for the conversion of lattices to bridged Ts but are too lengthy to be included here. These may be found in the works of Zobel, Bode, Guillemin, and others.

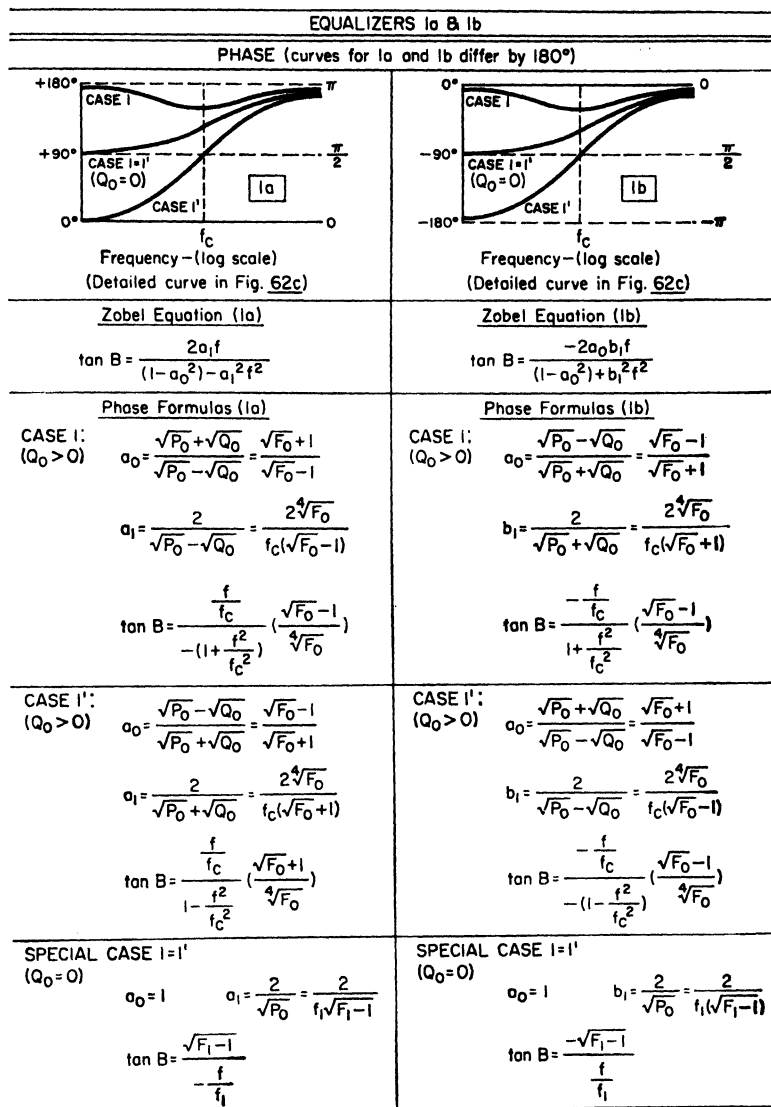
39. Constant-resistance Networks. A section of recurrent network having full series impedance of Z_{11} and full shunt impedance of Z_{21} is of constant-resistance type when $Z_{11}Z_{21} = R_0^2$. Its iterative impedance is equal to R_0. It follows that, when


FIG. 61b. Equalizers.

the output terminals of a constant-resistance network are terminated in a resistive load R_0, the input impedance also equals R_0 at all frequencies.

The impedance Z_{11} for the types of networks considered in this chapter is limited to combinations of L, C, and R. In a constant-resistance structure, Z_{11} and Z_{21} are inverse two-terminal networks, with respect to R_0^2 (see Sec. 36).

Constant-resistance networks have advantages in communications circuits, particularly when used as equalizers, phase correctors, and predistorting devices. There

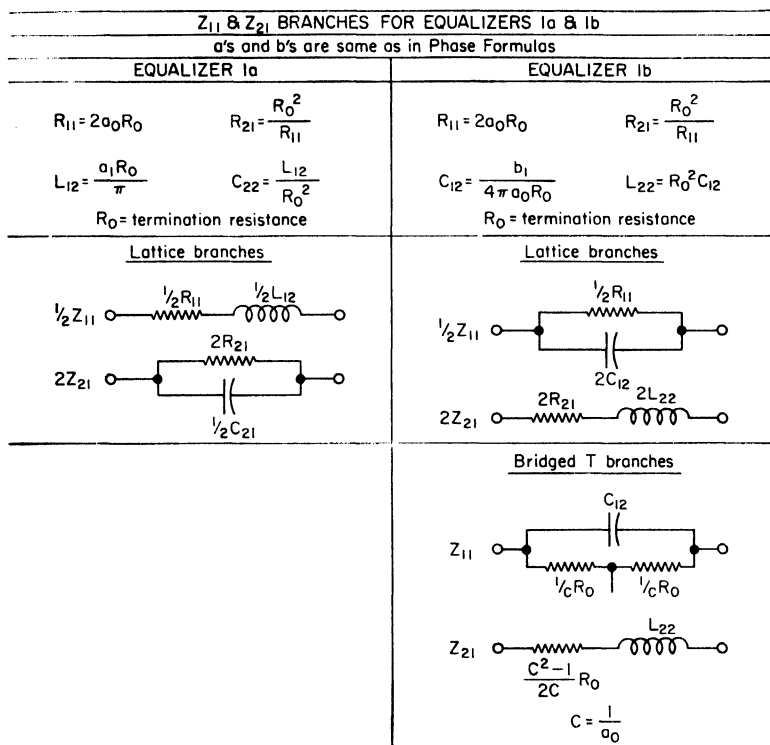
is usually some point in a communications system where the impedance looking toward the load is resistive and equal to the impedance looking toward the source, *i.e.*, "matched." At any such point, one or more constant-resistance networks of identical resistance may be inserted without disturbing the matched condition. This avoids reflection and interaction losses, so that insertion loss and phase shift introduced by the network are simply obtained as the sum of its propagation constant $P = A + jB$ and that of the original circuit. Thus, when a properly terminated constant-resistance network is employed as a corrective network, its effect upon transmission is completely described by its attenuation constant A and its phase constant B. These constants form the basis for the design of the device.


FIG. 61*c*. Equalizers.

40. Equalizers. An equalizer is a corrective network whose principal function is to alter the attenuation vs. frequency response of a communications circuit. Most equalizers have also an inherent phase characteristic that is by nature associated with their attenuation-frequency curves. Hence, if both equalization and phase correction are to be applied to a circuit, the equalizer should be designed first so that its contribution to the total phase shift can be included in the phase corrector.

As a basic unit for design purposes, the constant-resistance lattice is convenient. Some lattices—but not all—are convertible into constant-resistance bridged Ts for use in unbalanced circuits. The constant-resistance feature readily permits two or more sections having different characteristics to be joined in tandem, to achieve composite effects not obtainable with a single section.

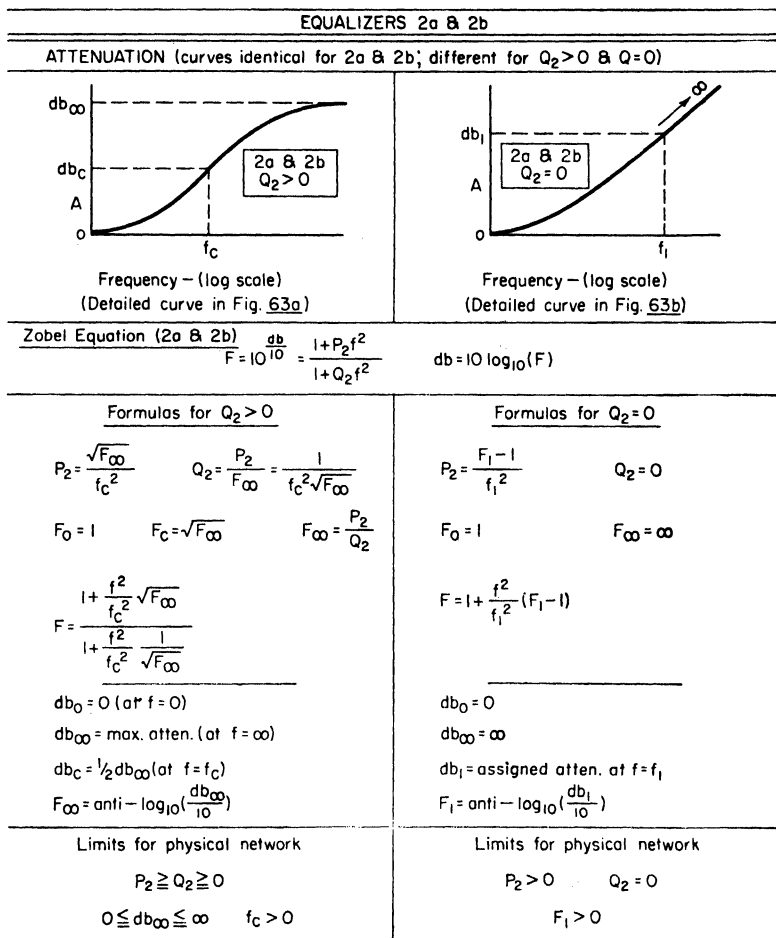
One method of finding a network that will produce the required attenuation and phase characteristics consists of selection by comparison with a number of structures whose characteristics have been previously computed and plotted. From a reasonably complete list of this sort, equalizers for many ordinary applications may be designed. This is the basis of the equalizer-design data in Sec. 41. When more exacting specifications have to be met, the techniques of network synthesis are employed. These methods are too lengthy a subject to be included in a general handbook but are available in the works of Bode, Guillemin, and others.


FIG. 61*d*. Equalizers.

In an excellent analysis of constant-resistance equalizers and phase correctors, Zobel[1] derived linear equations of the form

$$F \equiv e^{2A} = 10^{\frac{db}{10}} = \frac{P_0 + P_2 f^2 + \cdots}{Q_0 + Q_2 f^2 + \cdots}$$

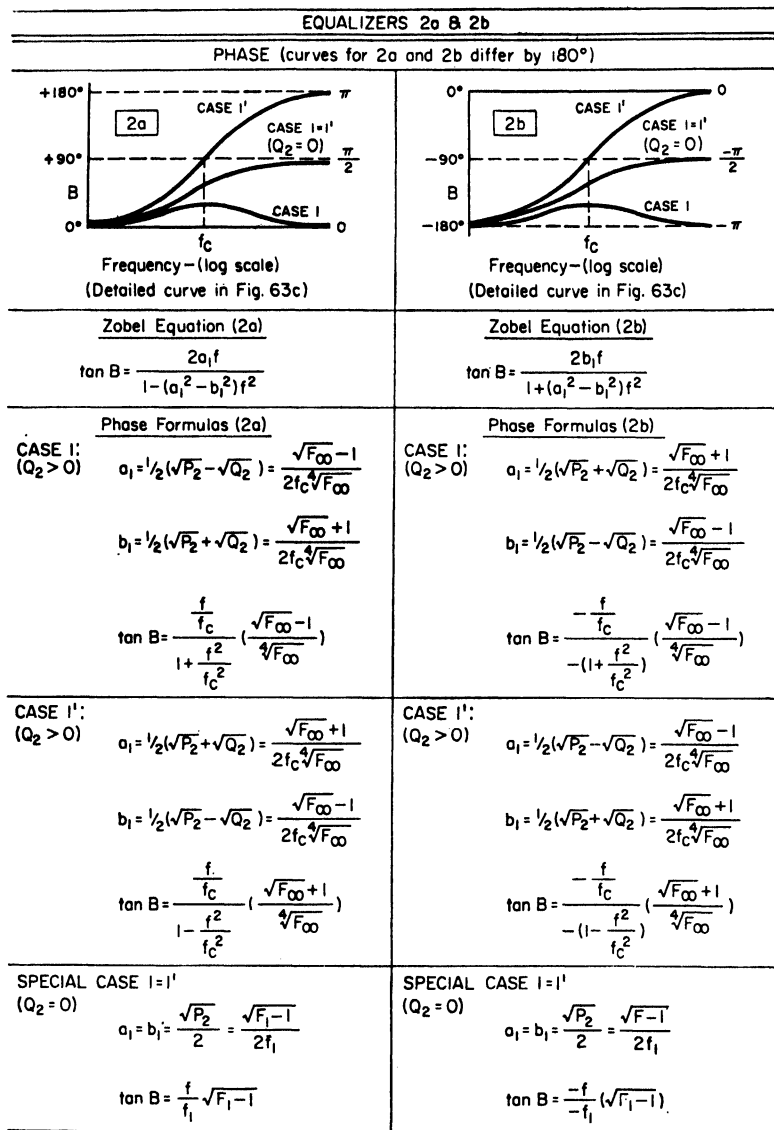
[1] *Ibid*


FIG. 61*e*. Equalizers.

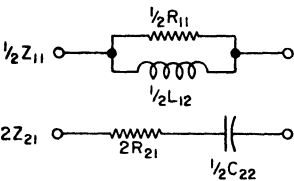
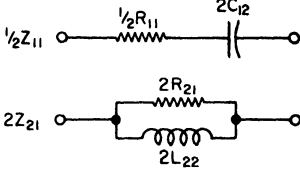
for a number of explicit lattice networks. *F* is an amplitude-transfer factor, *A* the attenuation constant, db the attenuation; the *P*s and *Q*s are constants for a given lattice under given conditions, and *f* is the frequency in cycles. Substitution of pairs of values for attenuation and frequency according to the characteristic desired yields a set of equations to be solved first for the *P*s and *Q*s, and eventually for the lattice impedances in terms of *L*, *C*, and *R*.

In some cases, more than one set of L, C, and R values will satisfy the equations, thus permitting some choice of the attenuation and phase characteristic. In the design data of Sec. 41, these conditions are designated as Case 1, Case 1′, etc.

Certain of Dr. Zobel's results are used here, by permission, in the sections on equalizer and phase-corrector design, and in the lattice-to-bridged-T transformation of Sec. 38.

41. Equalizer-design Data. The tables in Fig. 61 list the Zobel equations for attenuation and phase shift of four constant-resistance lattice equalizers. In addi-




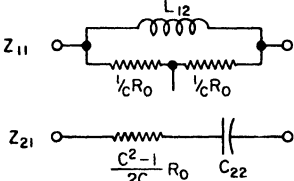


FIG. 61*f*. Equalizers.

tion, alternative relations are given, in terms of maximum and half-maximum attenuation. The latter are derived from the Zobel equations and offer somewhat shorter design formulas, but at the expense of some freedom of choice of points on the attenuation-frequency curves.

The tables also show the Z_{11} and Z_{21} branches for the lattice section (Fig. 60*a*) and for bridged-T equivalents (Fig. 60*e*) where they exist. Detailed attenuation and phase curves are shown in Figs. 62 to 65.

Space limitations prevent the inclusion here of more than these simpler forms of equalizers that are nevertheless useful in many ordinary applications. For more critical requirements and more complete techniques in the art of equalizer design, reference should be made to the works of Bode, Guillemin, etc.
FIG. 61*g*. Equalizers.

To use the design data in this section, after the attenuation characteristic required of the equalizer has been determined:

1. Select from the table an attenuation curve that most nearly fits the required characteristic. (Note that the symbolic curves of the table are plotted against log scales for frequency and therefore appear to be symmetrical; on a linear scale they are not symmetrical.)

2. Choose the *a* or *b* form of the equalizer, on the basis of phase curves. Attenuation curves from both forms are identical, but the phase characteristics differ by 180 deg. If a bridged-T final form is desired, one of the forms 1b, 2a, or 3a should be used; these can be transformed to physical bridged Ts.

3. Use the design formulas to compute branch impedance values.

4. Compute phase characteristic from the tan *B* formula. NOTE: To determine the quadrant of the phase angle, carry through the negative signs attached to numerator and
FIG. 61h. Equalizers.

denominator of the tan B equation to the final numerical result. The quadrant in which the angle lies can then be determined by the following table.

Numerator	Denominator	Quadrant
+	+	First
+	−	Second
−	−	Third
−	+	Fourth

Examples of Design of Equalizer:

1. Equalizer type 2a to have 4 db attenuation at 500 cycles, 10 db attenuation at 5,000 cycles, and $R_0 = 1{,}000$ ohms. Using Zobel attenuation equations,

$$F_{500} = 10^{0.4} = 2.512 = \frac{1 + P_2(500)^2}{1 + Q_2(500)^2}$$

$$F_{5,000} = 10^{1.0} = 10 = \frac{1 + P_2(5{,}000)^2}{1 + Q_2(5{,}000)^2}$$

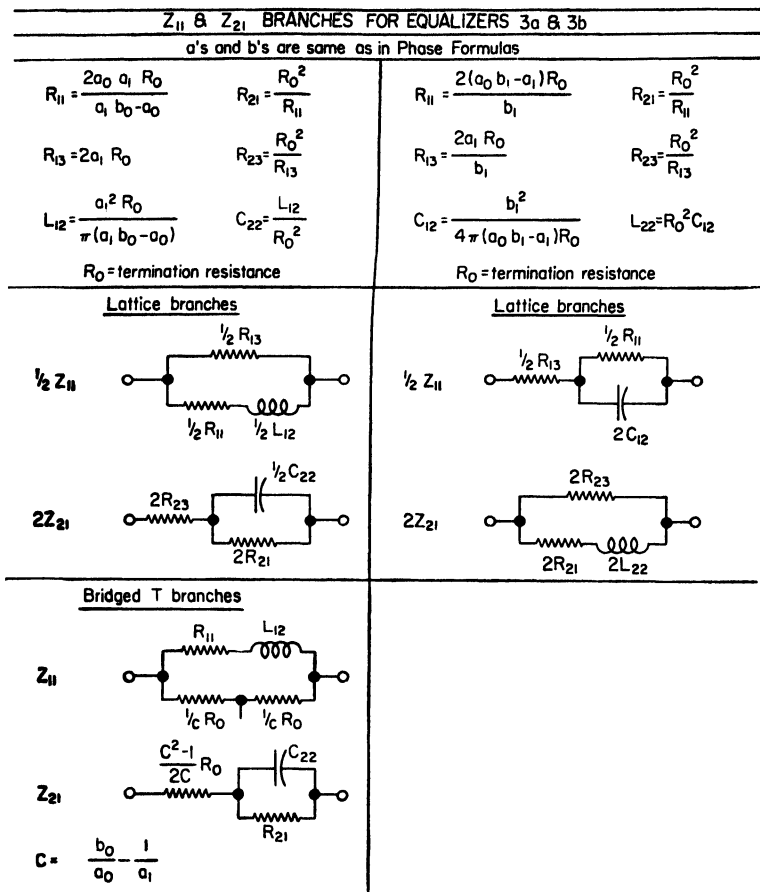
These yield $P_2 = 7.956 \times 10^{-6}$ and $Q_2 = 0.7596 \times 10^{-6}$.


Fig. 61*i*. Equalizers.

Using Case 1 conditions:

$$a_1 = \tfrac{1}{2}(\sqrt{P_2} - \sqrt{Q_2}) = 0.9747 \times 10^{-3}$$

and

$$b_1 = \tfrac{1}{2}(\sqrt{P_2} + \sqrt{Q_2}) = 1.8463 \times 10^{-3}$$

$$R_{11} = \frac{2a_1R_0}{b_1} = 1{,}055.8 \text{ ohms}$$

$$R_{21} = \frac{R_0^2}{R_{11}} = 947.1 \text{ ohms}$$

$$L_{12} = \frac{a_1R_0}{\pi} = 0.3103 \text{ henry}$$

$$C_{22} = \frac{L_{12}}{R_0^2} = 0.3103 \times 10^{-6} \text{ farad}$$

$$\tan B = \frac{2a_1f}{1 - (a_1^2 - b_1^2)f^2} = \frac{1.9494f}{1 + 4.359f^2}$$

Numerator and denominator are both positive; so B lies in first quadrant for all positive values of f.
FIG. 61*j*. Equalizers.

Transformation to bridged T, in accordance with Sec. 38:

Let
$$\frac{2R_0}{c} = R_{11} \text{ of lattice} = \frac{2a_1R_0}{b_1}$$
$$c = \frac{b_1}{a_1} = 1.8942$$
$$\frac{1}{c}R_0 = 527.9$$
$$\frac{c^2 - 1}{2c}R_0 = 683.1$$

The completed lattice and bridged-T equalizers are shown in Fig. 66.

2. Equalizer type 2a to have 14 db maximum attenuation at $f = \infty$ and ½ maximum attenuation at $f_c = 1{,}000$ cycles, with $R_0 = 1{,}000$ ohms.

Using formulas for 2a, $Q_2 > 0$:

$$F_\infty = 10^{1.4} = 25.12$$

$$P_2 = \frac{\sqrt{F_\infty}}{f_c^2} = 5.012 \times 10^{-6}$$

$$Q_2 = \frac{P_2}{F_\infty} = 0.1996 \times 10^{-6}$$

The balance of the computation is similar to that of the first example.

42. Degenerate Forms of Equalizers. Several simplified versions of equalizers, requiring fewer elements to construct than the full-section constant-resistance types,
FIG. 61*k*. Equalizers.

are shown in Fig. 67. In each case, either the series or shunt reactance arms are omitted. The branches retained are identical with corresponding ones in the full lattice in *a* and *b*, or with those of a bridged T in *c* and *d*. Resistances equal to R_0 are substituted for the omitted branches in *a* and *b*, resulting in 6 db additional insertion loss for these as compared with a full lattice structure.

These degenerate forms have the same attenuation characteristics as their corresponding full-section lattices or bridged Ts, but only when used between terminations each exactly equal to R_0. Since they are not in themselves constant-resistance devices, they do not present proper resistive terminations for other networks, and

FIG. 62c. Typical phase curves for equalizers 1a and 1b.

this precludes their use in tandem with other sections. Their chief advantage therefore lies in their economy for use as single sections in simple applications.

43. Phase Correctors. A constant-resistance lattice whose branches are pure reactances theoretically has no attenuation at any frequency, so is an all-pass network. The absence of attenuation while at the same time a phase characteristic is retained makes this type of network useful for phase correction. Data on several lattices of this type were published by Zobél,[1] and his equations for the following two forms are reproduced here by permission.

[1] *Ibid.*
FIG. 63a. Typical attenuation curves for equalizers $2a$ and $2b$, $Q_2 > 0$.
FIG. 63b. Typical attenuation curves for equalizers $2a$ and $2b$, $Q_2 = 0$.

Phase Corrector I. The lattice circuit is shown in Fig. 68, and a typical phase curve in Fig. 69. The basic equations are:

$$\tan \tfrac{1}{2} B = a_1 f \tag{99}$$

$$L_{11} = \frac{a_1 R_0}{\pi} \tag{100}$$

$$C_{21} = \frac{L_{11}}{R_0^2} = \frac{a_1}{\pi R_0} \tag{101}$$

where R_0 = source and load resistances (equal)
B = phase difference, output vs. input
a_1 = constant to be assigned, determining slope of phase characteristic
f = frequency, cps

In one sense, the shape of the phase curve for this lattice is fixed, since the slope is proportional to frequency for any given a_1. The design problem, then, is merely to
FIG. 63c. Typical phase curves for equalizers 2a and 2b.
FIG. 64a. Typical attenuation curves for equalizers 3a and 3b.

evaluate a_1 to produce the desired phase angle at a specified frequency. This choice of a_1 then automatically determines the phase curve for all other frequencies.

Phase Corrector II. This lattice is shown in Fig. 70 and typical phase curves in Fig. 71. The basic equations are:

$$\tan \tfrac{1}{2} B = \frac{a_1 f}{1 - b_2 f^2} \tag{102}$$

$$L_{11} = \frac{a_1 R_0}{\pi} \tag{103}$$

$$C_{12} = \frac{b_2}{4\pi a_1 R_0} \tag{104}$$

$$C_{21} = \frac{L_{11}}{R_0^2} = \frac{a_1}{\pi R_0} \tag{105}$$

$$L_{22} = R_0^2 C_{12} = \frac{b_2 R_0}{4\pi a_1} \tag{106}$$
FIG. 64b. Phase curves for equalizers $3a$ and $3b$.
FIG. 65a. Typical attenuation curves for equalizers $4a$ and $4b$.

The symbols are the same as for type I, except for the additional constant b_2 to be assigned.

The presence of two arbitrary constants in Eq. (102) imparts some flexibility to the shape of the phase curve for this network. For design purposes, the substitution of two sets of values for phase angle and frequency into Eq. (102) will yield a pair of equations to evaluate a_1 and b_2. It should be noted that

$$f = \frac{1}{\sqrt{b_2}} \tag{107}$$

is the frequency at which the phase difference is 180 deg.

Conversion of all-pass lattices into bridged-T networks is discussed by Zobel, Bode, Guillemin, and others in the references, but the process involves additional techniques too lengthy to be included here.

TRANSMISSION LINES

44. General Properties of Transmission Lines. All the relations in this section apply to any smooth transmission line with uniformly distributed constants and are exact except that radiation and end effects are not taken into account.

Characteristic impedance is equivalent to the input impedance of an infinitely long line and is

$$Z_0 = \sqrt{\frac{R + j\omega L}{G + j\omega C}} \quad \text{ohms} \tag{108}$$

or

$$|Z_0| = \sqrt[4]{\frac{R^2 + \omega^2 L^2}{G^2 + \omega^2 C^2}} \quad \text{ohms (magnitude)} \tag{109}$$

or

$$Z_0 = \sqrt{Z_{oc} Z_{sc}} \quad \text{ohms} \tag{110}$$

where Z_{oc} and Z_{sc} are the line input impedances with the far end open- and short-circuited, respectively, and R, L, G, and C are the resistance, inductance, leakage conductance, and capacitance of the line per unit of physical length. For practical purposes any convenient unit length such as 1 ft or 1 cm may be used. The same unit length must be used throughout any one computation, however.

The ratio of the currents I_1 and I_2 at points along the line one unit length apart is determined by the *propagation constant,* which is

$$P \text{ per unit length} = \log_\epsilon \frac{I_1}{I_2} = \sqrt{(R + j\omega L)(G + j\omega C)}$$
$$= A + jB \qquad (111)$$

Attenuation Constant. The real part A of P determines the relative magnitude of I_1/I_2 and is

$$A = 6.141 \sqrt{\sqrt{(R^2 + \omega^2 L^2)(G^2 + \omega^2 C^2)} + RG - \omega^2 LC} \quad \text{db/unit length} \qquad (112)$$

Wavelength Constant. The quadrature part B of P determines the relative phase of I_1/I_2 and is

$$B = 0.707 \sqrt{\sqrt{(R^2 + \omega^2 L^2)(G^2 + \omega^2 C^2)} - RG + \omega^2 LC} \quad \text{radians/unit length} \qquad (113)$$

To obtain the value in degrees per unit length, change the constant before the radical in Eq. (113) from 0.707 to 40.51.

Velocity of propagation is

$$V = \frac{\omega}{B} = \frac{2\pi f}{B} \quad \text{unit lengths/sec} \qquad (114)$$

Wavelength is

$$\lambda = \frac{2\pi}{B} \quad \text{unit lengths} \qquad (115)$$

Retardation time or *delay* is

$$t = \frac{B}{\omega} = \frac{B}{2\pi f} \quad \text{sec/unit length} \qquad (116)$$

Line Terminated in Any Impedance Z_R. The input impedance is

$$Z_i = \frac{E_s}{I_s} = Z_0 \frac{Z_R \cosh Pl + Z_0 \sinh Pl}{Z_0 \cosh Pl + Z_R \sinh Pl}$$
$$= Z_0 \frac{Z_R/Z_0 + \tanh Pl}{1 + (Z_R/Z_0) \tanh Pl} \quad \text{ohms} \qquad (117)$$

where l = length of line in unit lengths
P = propagation constant per unit length
Z_R = receiving end termination impedance
Z_0 = characteristic impedance of line
Z_i = input impedance of line
E_s and I_s = voltage and current at sending end

Current at any point x unit lengths from sending end in terms of sending end current is

$$I_x = I_s \left(\cosh Px - \frac{Z_i}{Z_0} \sinh Px\right) \quad \text{amp} \qquad (118)$$

Voltage at any point x unit lengths from sending end in terms of sending end voltage is

$$E_x = E_s \left(\cosh Px - \frac{Z_0}{Z_i} \sinh Px\right) \quad \text{volts} \qquad (119)$$

In this case, the current and voltage along the line vary from point to point because of standing waves. (See Sec. 58 for conditions in r-f lines.)

Lines Terminated in Impedance Z_0. The input impedance for any length of line is

$$Z_i = Z_0 \quad \text{ohms} \tag{120}$$

Current or voltage at any point x unit lengths from sending end in terms of sending end current or voltage is

$$\frac{E_x}{E_s} = \frac{I_x}{I_s} = \epsilon^{-\Gamma x} = \epsilon^{-Ax}\epsilon^{-jBx} = \epsilon^{-Ax}(\cos Bx - j \sin Bx) \tag{121}$$

The ratio of voltage to current at any point x along the line is

$$\frac{E_x}{I_x} = Z_0 \tag{122}$$

In the communication field, transmission lines may be classified according to the frequency bands that they are required to transmit, as *audio-* or *radio-frequency* lines. Simplified forms of the general transmission line formulas result from the introduction of approximations that are appropriate to each case.

45. Terminating Conditions for No Reflections and Maximum Power Transfer. Conditions for maximum power transfer through a transmission line call for the source and load impedances to be the *conjugates*, respectively, of the line input impedances as seen from each end of the line with the opposite termination connected. Conditions for no reflections at the ends of the line call for source and load impedances to be *equal* to the line characteristic impedance. These conditions are mutually incompatible if the line Z_0 is not pure resistance. In the general case where Z_0 has a reactance component, the best terminating impedances are a compromise between efficient energy transfer and the avoidance of reflections. Fortunately, in practical r-f lines Z_0 is very nearly a pure resistance so that both conditions are satisfied by making the source and load impedances pure resistances each equal to Z_0.

Radio-frequency lines whose terminal impedances are not equal to Z_0 are inefficient for two reasons: (1) they do not deliver maximum power to the load, and (2) some energy is reflected at each mismatched junction. Any impedance irregularity along the line also produces reflections and should usually be avoided. Thus, bends in an open-wire line should be gradual, with a minimum radius of about $\lambda/4$, and the line should be kept clear by at least $\lambda/4$ from large masses of conducting or dielectric materials, including ground.

The amount of reflection produced by a terminating impedance Z_T at the receiving end of a line of characteristic impedance Z_0 is expressed by the *reflection coefficient*

$$k = \frac{Z_T - Z_0}{Z_T + Z_0} = \frac{(Z_T/Z_0) - 1}{(Z_T/Z_0) + 1} \tag{123}$$

In lines whose principal purpose is conveyance of energy from one terminal to the other, reflections are objectionable because of increased ohmic and radiation losses. Also, the current and voltage peaks associated with the resulting standing waves must be considered in relation to conductor size and line insulation. The magnitude of the standing waves is given by the *standing-wave ratio* (SWR),

$$\text{SWR} = \frac{E_{\max}}{E_{\min}} = \frac{I_{\max}}{I_{\min}} = \frac{1 + |k|}{1 - |k|} \tag{124}$$

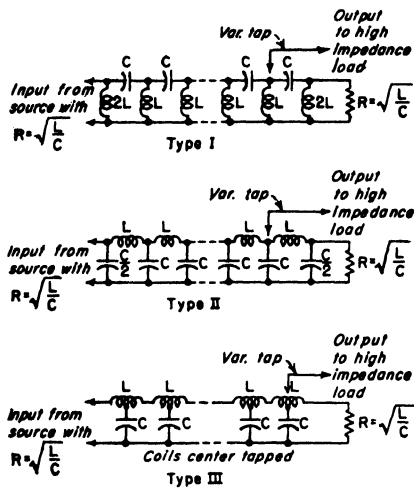
where $|k|$ is the positive value of the magnitude of the reflection coefficient as defined in Eq. (123), and the Es and Is refer to maximum and minimum voltages and currents on the line.

If the line attenuation is large, Eq. (124) holds true only at points near the receiving end, since the SWR will vary along the line length. In a low-loss line, however,

the SWR is essentially constant throughout; so the receiving end reflection coefficient may be determined by SWR measurements at the sending end, with reasonable accuracy.

Various methods for measuring SWR in transmission lines are in use. For a two-wire open line, voltage or current measurements at the nodes and antinodes give the necessary data. For coaxial lines, slotted sections of line with calibrated sliding probes give accurate results. For continuous observation of standing-wave conditions, reflectometers[1] are most convenient. Various forms of this device are available commercially, and they usually include a calibrated indicator for power in the line.

Fig. 72. Delay networks.

46. Delay Networks. Three typical networks are shown in Fig. 72. It is assumed that each is fed from a source whose internal impedance is $R = \sqrt{L/C}$ and that it is terminated in a pure resistance of the same value. The delayed signal output is taken from a variable tap and fed to any device having an internal impedance which is large compared to R. Since networks I and II are respectively high- and low-pass filters of the constant-K type, they have amplitude attenuation characteristics as shown in Sec. 65. Network III has no cutoff frequency if coupling between the two halves of each coil is perfect. Relative delay vs. frequency characteristics of the three types of networks (using the same values of L and C in each case) are shown in Fig. 73. The following relations are based on resistanceless networks and hold within about 1 per cent if the coil Q is 20 or more and the capacitor Q is 100 or more.


$$R = \sqrt{\frac{L}{C}} \quad \text{(approx) for all three networks} \tag{125}$$

Network I. Amplitude attenuation is large up to

$$f_c = \frac{1}{4\pi \sqrt{LC}} \quad \text{cycles} \tag{126}$$

and is zero thereafter (high-pass).

Delay for $f \leqq f_c$ is

$$t = \frac{1}{2f} \quad \text{sec/section} \tag{127}$$

Delay for $f > f_c$ is

$$t = \frac{2}{\omega} \sin^{-1} \frac{1}{2\omega \sqrt{LC}} \quad \text{sec/section exactly (angle in radians)} \tag{127a}$$

$$= \frac{1}{\omega^2 \sqrt{LC}} + \frac{1}{\omega}\left[0.04167 \left(\frac{1}{\omega \sqrt{LC}}\right)^3 + 0.00468 \left(\frac{1}{\omega \sqrt{LC}}\right)^5 + 0.000698 \left(\frac{1}{\omega \sqrt{LC}}\right)^7\right] \quad \text{sec/section (approx)} \tag{127b}$$

[1] Korman, Nathaniel I., Note on a Reflection-coefficient Meter, *Proc. IRE*, September, 1946, p. 657.
FIG. 73. Delay vs. frequency characteristics of three types of delay networks using the same LC in each.

Delay for $f \gg f_c$ is

$$t = \frac{1}{\omega^2 \sqrt{LC}} \quad \text{sec/section (approx)} \tag{127c}$$

Network II. Amplitude attenuation is zero up to cutoff frequency

$$f_c = \frac{1}{\pi \sqrt{LC}} \quad \text{cycles} \tag{128}$$

and is large thereafter (low-pass).

Delay for $f < f_c$ is

$$t = \frac{2}{\omega} \sin^{-1} \frac{\omega}{2} \sqrt{LC} \quad \text{sec/section exactly (angle in radians)} \tag{128a}$$

$$= \sqrt{LC} + \frac{1}{\omega} [0.04167(\omega \sqrt{LC})^3 + 0.00468(\omega \sqrt{LC})^5 + 0.000698(\omega \sqrt{LC})^7]$$

sec/section (approx)

Delay for $f \ll f_c$ is

$$t = \sqrt{LC} \quad \text{sec/section (approx)} \tag{128b}$$

Delay for $f \geqq f_c$ is

$$t = \frac{1}{2f} \quad \text{sec/section (approx)} \tag{128c}$$

Network III. Amplitude attenuation is zero at all frequencies for 100 per cent coupling between the two halves of each coil. In practice, this condition cannot be attained, and the attenuation will increase gradually with frequency.

Delay for all frequencies is

$$t = \frac{1}{\omega} \cos^{-1} \frac{4 - \omega^2 LC}{4 + \omega^2 LC} \quad \text{sec/section (angle in radians)} \tag{129}$$

By reference to Fig. 73 it is evident that the delay for networks II and III is constant to within ±5 per cent for all frequencies up to that indicated as relative frequency = 1. This value corresponds to $f = 1/(2\pi\sqrt{LC})$ for the network characteristics shown in the figure.

The principal use of network I is to obtain large delays at a single frequency, since in the vicinity of $f = 0.55/(2\pi\sqrt{LC})$ (relative frequency = 0.55 in Fig. 73) it produces about four times as much delay per section as II or III with the same coils and capacitors.
Fig. 74. Example of low-pass delay network used in television pulse circuits.

A practical application of a delay network of type II, as used in the formation of television synchronizing pulses, is illustrated in Fig. 74. With the constants shown the delay is 0.235 μsec per section for all frequencies up to about 680 kc.

47. *RC* Filter for Small Currents. An economical *RC* filter for small currents as suggested by Scott[1] is shown in Fig. 75. A special feature is the shunting circuit through R_A to feed voltage 180 deg out of phase to the point X. This can be adjusted to give a very high attenuation at one particular frequency which it is desired to eliminate. As shown, this filter is low-pass; a similar high-pass structure can be made by transposing the *R*'s and *C*'s.
Fig. 75. *RC* filter for small currents.

48. Resistance Pads. Resistance pads are artificial lines whose series and shunt elements are pure resistances and are used principally as attenuators in a-f circuits. The amount of loss caused by insertion of a pad in a circuit may be accurately computed and is independent of frequency if the terminating impedances are resistances.

Either π or T structures may be used as pads, as shown in Fig. 76*a*. Both are electrically equivalent, but for identical values of loss and impedance one type may require resistors of more convenient values than the other. A pad to be used in a circuit that is balanced to ground should be of the balanced π or T type; otherwise the unbalanced network is satisfactory and requires several less resistors to build.

49. Pad Design. To design a pad, three constants must be known: the input and output impedances and the loss in decibels. The input and output impedances of a pad are usually made equal to those of the circuit to be connected to it. The design procedure depends upon whether these are equal or are different from each other.

1. *Equal Input and Output Impedances.* In this case, the value of each element is found by multiplying the proper constants, selected from Table 1 in connection with Fig. 76*a*, by the value of the input or output impedance Z in ohms.

Example: To design a 10-db, 500/500-ohm pad of the balanced T type: From Table 1, for 10-db attenuation, $a = 0.5195$ (hence $a/2 = 0.2597$) and $b = 0.7027$. Then the required resistances are $0.2597 \times 500 = 129.85$ for the series elements and $0.7027 \times 500 = 351.35$ ohms for the shunt element.

2. *Unequal Input and Output Impedances.* In this case, the design involves more computation. The value of each element is indicated by Fig. 76*b*, the constants of which are to be found in Table 1. The ratio of input to output impedance (or vice versa) of a pad of given loss is limited by the fact that, for large values of the impedance

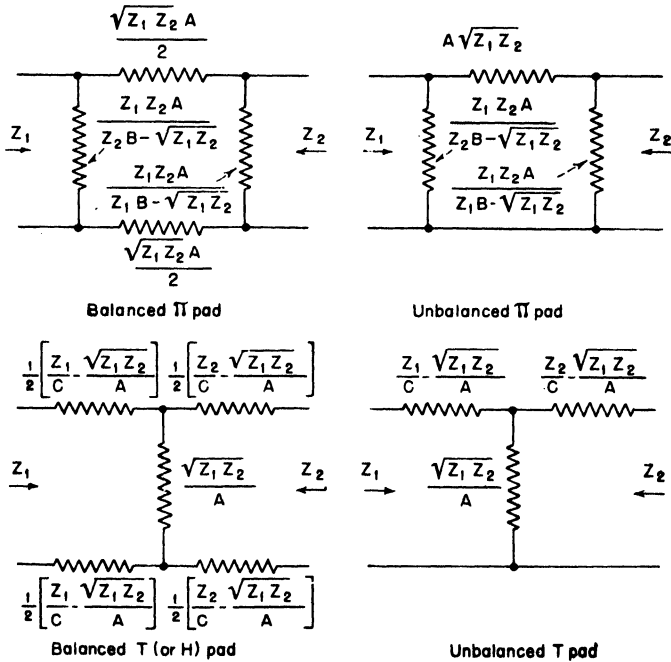
[1] Scott, H. H., *Electronics*, August, 1939.
FIG. 76*a*. Pads to be used between equal impedances.


FIG. 76*b*. Pads to be used between unequal impedances.

ratio, certain of the pad resistors would have to be negative in value if the loss of the pad were to be below a certain minimum value. The maximum impedance ratio which a 10-db pad can have, for example, is 3.018. Stated in another way, this means that, if the impedance ratio of a pad is to be 3.018, its loss must be at least 10 db. The maximum impedance ratios for various values of pad losses are also given in Table 1. These are the same for both π and T pads.

Table 1. Constants for Pads of Fig. 76

$$A = \sinh \theta \qquad a = \frac{1}{C} - \frac{1}{A}$$

$$B = \cosh \theta$$

$$C = \tanh \theta \qquad b = \frac{1}{A}$$

$$\theta = \frac{\text{loss in db}}{8.686} \qquad \text{Max ratio } \frac{Z_1}{Z_2} \text{ or } \frac{Z_2}{Z_1} = B^2$$

Example: To design a 20-db 500/200-ohm pad of the unbalanced π type:

$$Z_1 = 500 \text{ ohms} \qquad Z_2 = 200 \text{ ohms}$$

From Table 1, $A = 4.9522$ and $B = 5.0522$. Then,

$$\text{Input shunt element} = \frac{Z_1 Z_2 A}{Z_2 B - \sqrt{Z_1 Z_2}} = 713 \text{ ohms}$$

$$\text{Series element} = \sqrt{Z_1 Z_2} A = 1{,}567 \text{ ohms}$$

$$\text{Output shunt element} = \frac{Z_1 Z_2 A}{Z_1 B - \sqrt{Z_1 Z_2}} = 430 \text{ ohms}$$

50. General Properties of R-f Lines. Useful working formulas for r-f lines are obtained by making use of the fact that at radio frequencies ωL and ωC become very large in comparison with R and G, respectively. The results are approximations whose accuracy depends upon whether R and G are treated as zero or as small quantities.

Symbols used in r-f line relations:

L = inductance, henrys/unit length
C = capacitance, farads/unit length
R = series resistance, ohms/unit length
G = shunt conductance, mhos/unit length

NOTE: L, C, R, and G are values for one unit length of two conductors.

V = actual velocity of propagation
V.F. = velocity factor, actual velocity as fraction or per cent of speed of light
v = speed of light, 3×10^8 meters/sec
ω = $2\pi \times$ frequency, cycles
f = frequency, cycles
f_{Mc} = frequency, megacycles
d_o = inner diam of outer conductor } both in same units
d_i = outer diam of inner conductor } both in same units
d = diam of conductor } both in same units
s = spacing between conductors, center to center } both in same units
l = length of line in unit lengths
Unit length = arbitrary small length of line, as 1 cm or 1 ft
in. = (as subscript) dimensions in inches

1. *Dissipationless R-f Lines.* ($R = 0$ and $G = 0$; approximate conditions for air-insulated copper lines.)

Characteristic impedance is

$$Z_0 = \sqrt{\frac{L}{C}} = \frac{1}{vC} \quad \text{ohms} \tag{130}$$

Velocity of propagation is

$$V = \frac{1}{\sqrt{LC}} \quad \text{unit lengths/sec}$$
$$= v = 3 \times 10^8 \text{ meters/sec} \tag{131}$$

Propagation constant is

$$P = jB = j\omega\sqrt{LC} \tag{132}$$

Wavelength constant is

$$B = \omega\sqrt{LC} = \omega C Z_0 \quad \text{radians/unit length}$$
$$= \frac{\omega}{v} = 2.0944 \times 10^{-8} f \quad \text{radians/meter} \tag{133}$$

Wavelength (physical distance) is

$$\lambda = \frac{2\pi}{\omega\sqrt{LC}} = \frac{1}{f\sqrt{LC}} \quad \text{unit lengths}$$
$$= \frac{v}{f} = \frac{3 \times 10^8}{f} = \frac{300}{f_{Mc}} \quad \text{meters} \tag{134}$$

Retardation time or *delay* is

$$t = \frac{B}{\omega} = \sqrt{LC} \qquad \text{sec/unit length}$$

$$= \frac{1}{v} = 0.333 \times 10^{-8} \qquad \text{sec/meter} \tag{135}$$

2. *R-f Lines with Small Attenuation.* ($R \neq 0$ and $G \neq 0$; approximate conditions for lines with dielectrics other than air.)

Attenuation is

$$A = 4.343\left(R\sqrt{\frac{C}{L}} + G\sqrt{\frac{L}{C}}\right) = 4.343\left(\frac{R}{Z_0} + GZ_0\right) \qquad \text{db/unit length} \tag{136}$$

The other constants for lines with small attenuation are

$$Z_0 = \sqrt{\frac{L}{C}}\left[1 + j\left(\frac{G}{2\omega C} - \frac{R}{2\omega L}\right)\right] \qquad \text{ohms} \tag{137}$$

$$V = \frac{\text{V.F.}}{\sqrt{LC}} \qquad \text{unit lengths/sec}$$

$$= v \times \text{V.F.} \qquad \text{meters/sec} \tag{138}$$

$$B = \frac{\omega\sqrt{LC}}{\text{V.F.}} \qquad \text{radians/unit length}$$

$$= \frac{2.09 \times 10^{-8} f}{\text{V.F.}} \qquad \text{radians/meter} \tag{139}$$

$$\lambda = \frac{\text{V.F.}}{f\sqrt{LC}} \qquad \text{unit lengths}$$

$$= \frac{3 \times 10^8}{f} \times \text{V.F.} = \frac{300}{f_{\text{Mc}}} \times \text{V.F.} \qquad \text{meters} \tag{140}$$

$$t = \frac{\sqrt{LC}}{\text{V.F.}} \qquad \text{sec/unit length}$$

$$= \frac{0.333 \times 10^{-8}}{\text{V.F.}} \qquad \text{sec/meter} \tag{141}$$

Although it is possible to calculate the velocity factor (V.F.) approximately for a given line, usually it is more practical to use the actually measured value. See Sec. 57 and Table 2.

The foregoing relations are equally applicable to coaxial and parallel wire lines. For lines of specified configurations, L, C, and R can be evaluated in terms of physical dimensions to give the relations that follow. G is not readily computed and, if it is not negligible, should preferably be measured.

3. *Parallel Two-wire Open R-f Line.* (Neither side grounded; copper conductors; R and G small.)

$$Z_0 = 277 \log_{10} \frac{2s}{d} \qquad \text{ohms} \tag{142}$$

This holds if $s \geqq 10d$ and the height above ground is $10s$ or more. Values of Z_0 for various conductor sizes and spacings are shown in Fig. 77.

$$A = 0.867 \frac{\sqrt{f_{\text{Mc}}}}{d_{\text{in.}} \times Z_0} \qquad \text{db/100 ft} \tag{143}$$
FIG. 77. Z_0 for balanced parallel copper-conductor r-f lines.

where $d_{in.}$ is the conductor diameter in inches. Equation (143) is based solely on copper losses and neglects all other losses. For accurate results, measured values are preferable to calculated values.

Storage factor is

$$Q = \frac{\omega L}{R} = 883.9 d_{in.} \times \sqrt{f_{Mc}} \times \log_{10} \frac{2s}{d} \tag{144}$$

Maximum voltage gradient is the same for both wires, occurs at the surface of each wire and at the point nearest the opposite wire, and is

$$\text{grad}_{max} = \frac{0.342E}{d_{in.} \times \log_{10} (2s/d)} \quad \text{volts/cm} \tag{145}$$

where E is the voltage between the wires at the point in question.

4. *Coaxial Two-conductor R-f Line.* (Copper conductors; R and G small.)

$$Z_0 = 138.5 \log_{10} \frac{d_o}{d_i} \quad \text{ohms} \tag{146}$$

Values of Z_0 vs. the ratio d_0/d_i are shown in Fig. 78.

$$A = \frac{0.00313 \sqrt{f_{Mc}} [1 + (d_o/d_i)]}{d_{o\ in.} \log_{10} (d_o/d_i)} \quad \text{db/100 ft} \tag{147}$$

where $d_{o\ in.}$ is the diameter of the outer conductor in inches. Equation (147) is based solely on copper losses and neglects leakage conductance G. When G cannot be neglected, measurements are preferable to calculations.

$$Q = \frac{0.8863 d_{o\ in.} \sqrt{f_{Mc}} \log_{10} (d_o/d_i)}{1 + d_o/d_i} \tag{148}$$
FIG. 78. Z_0 and relative loss vs. ratio of diameters for coaxial lines.

Optimum Diameter Ratios for Copper Coaxial Lines*

Optimum quantity	d_o/d_i	Z_0, ohms
Max antiresonant Z	9.185	132.9
Max Q and min attenuation (see Fig. 78)	3.592	76.64
Max breakdown volts	2.718	59.93
Min temp. rise, inner conductor	1.835	36.38
Max power carrying capacity	1.648	29.94

* Smith, P. H., *Electronics*, February, 1950.

Maximum voltage gradient occurs at the surface of the inner conductor and is

$$\text{grad}_{\text{max}} = \frac{0.342E}{d_{i\ \text{in.}} \log_{10} (d_o/d_i)} \quad \text{volts/cm} \tag{149}$$

where E is the voltage between inner and outer conductors and $d_{i\ \text{in.}}$ is the diameter of the inner conductor in inches.

5. *Resistance of Copper R-f Lines.* For two-wire open lines,

$$R = \frac{0.1996\ \sqrt{f_{\text{Mc}}}}{d_{\text{in.}}} \quad \text{ohms/100 ft} \tag{150}$$

For coaxial lines,

$$R = \frac{0.0998\ \sqrt{f_{\text{Mc}}}\ [1 + (d_o/d_i)]}{d_{o\ \text{in.}}} \quad \text{ohms/100 ft} \tag{151}$$

In both cases, the resistance is in terms of 100 ft of line and takes into account the fact that there are two conductors.

51. RCA Six-wire Line. A type of open-wire line frequently used for feeding a broadcast transmitting antenna which operates with one side grounded is shown in Fig. 80. The four outer wires are connected together and grounded to act as one conductor, and the two inner wires are connected together to act as the second conductor. The outer wires function as a shield and limit radiation from the line to about 0.015 per cent in one wavelength of line as compared to about 1 per cent for an unbalanced two-wire line of corresponding dimensions. Ground conductivity losses are also reduced by using the six-wire line. The characteristic impedance using No. 6 copper conductors is 230 ohms, and the attenuation is approximately 0.04 $\sqrt{f_{Mc}}$ db per 100 ft throughout the 550- to 1,600-kc broadcast band for a soil conductivity of 50×10^{-15} emu.
FIG. 79. Typical construction on commercial coaxial types of r-f transmission lines.
FIG. 80. Six-wire r-f line with low radiation. (*RCA*.)

52. Impedance Relations in R-f Lines. At high frequencies the attenuation constant of a line is so small that it may be neglected in many cases to simplify impedance calculations. On this basis, Z_0 is essentially pure resistance, and the input impedance of a line terminated at its end in any impedance Z_T reduces, from Eq. (117), to

$$\begin{aligned} Z_i &= Z_0 \frac{Z_T \cos lB + jZ_0 \sin lB}{Z_0 \cos lB + jZ_T \sin lB} \\ &= Z_0 \frac{Z_T \cos 2\pi l/\lambda + jZ_0 \sin 2\pi l/\lambda}{Z_0 \cos 2\pi l/\lambda + jZ_T \sin 2\pi l/\lambda} \\ &= Z_0 \frac{Z_T/Z_0 + j \tan 2\pi l/\lambda}{1 + jZ_T/Z_0 \tan 2\pi l/\lambda} \quad \text{ohms} \end{aligned} \tag{152}$$

in which l is the length of the line and λ is the wavelength of the signal, both measured in the same unit of length. This gives the value of $2\pi l/\lambda$ in radians. It is often convenient to substitute the electrical length of the line in degrees for $2\pi l/\lambda$, on the basis of 360 deg per wavelength. Thus a $\lambda/4$ line represents 90 electrical degrees, etc.

Actual numerical computation of input impedance by Eq. (152) is a tedious process, especially if Z_T is not pure resistance. When many such computations are to be made, the transmission line calculator of P. H. Smith[1] is a practical timesaver. This device is in the form of a circular slide rule and also yields such information as standing-wave ratios and line attenuation.

Open-circuited Line. The input impedance of a no-loss line of any length open-circuited at its far end ($Z_T = \infty$) is a pure reactance

$$Z_i = -jZ_0 \cot lB = -jZ_0 \cot 2\pi l/\lambda \tag{153}$$

Short-circuited Line. The input impedance of a no-loss line of any length short-circuited at its far end ($Z_T = 0$) is a pure reactance

$$Z_i = jZ_0 \tan lB = jZ_0 \tan 2\pi l/\lambda \tag{154}$$

The reactive input impedance of a short length of line, or "stub" line, provides a handy method of balancing out unwanted reactance in the termination of a h-f line.

(a) $Z_i = Z_0^2/Z_T$

(b) $Z_0 = \sqrt{Z_T Z_S}$

(c) Two or more sections for broad-band matching
FIG. 81. Quarter-wave lines as impedance transformers. All sections are $\lambda/4$ at f_0.

The stub is connected in parallel across the terminating impedance and trimmed in length by trial until an increase in signal strength or similar indication shows that the desired result is obtained. Such stubs may be either open- or short-circuited at their free ends.

53. Properties of Quarter-wave R-f Lines. In dissipationless r-f lines the input impedance Z_i of a $\lambda/4$ line—and of all lines whose lengths are odd multiples of $\lambda/4$—is the reciprocal of its terminating impedance Z_T when the two impedances are expressed in terms of the line characteristic impedance Z_0 (Fig. 81). Thus

$$\frac{Z_i}{Z_0} = \frac{Z_0}{Z_T} \quad \text{or} \quad Z_i = \frac{Z_0^2}{Z_T} \tag{155}$$

This condition is independent of the value of the characteristic impedance Z_0 of the line.
FIG. 82. Support for antenna elements A made into form of $\lambda/4$ line, effectively insulating points a-a from ground.
FIG. 83. Use of $\lambda/4$ short-circuited line to by-pass low-frequency currents for melting sleet without disturbing the r-f impedance of the system.

If a $\lambda/4$ line is short-circuited at its far end ($Z_T = 0$), Z_i is very large, approaching ∞ in the case of a dissipationless line. This fact is made use of in such practical applications as the "conductive insulator," Fig. 82, and the sleet-melting arrangement shown in Fig. 83.

If a $\lambda/4$ line is open-circuited at its far end ($Z_T = \infty$), Z_i is very small, approaching zero for a dissipationless line. A practical application is the third-harmonic suppressor shown in Fig. 84, in which an open-circuited $\lambda/4$ line A (at third-harmonic frequency) is shunted across a line carrying a signal of fundamental frequency f. The stub line effectively short-circuits the main line for currents of frequency $3f$, thereby eliminating the third harmonic. However, the effect of the stub at the fundamental frequency f must also be considered. For this frequency, the stub length is $\lambda/12$, and the line presents a shunt reactance of $-j1.732Z_0$ ohms to currents of frequency f. To balance out this reactance a second stub B, of length $\lambda/6$ and short-circuited at its far end, is also shunted across the main line at the same point. This presents an equal and opposite reactance of $+j1.732Z_0$ ohms to resonate at frequency f with the reactance of stub A. Stub B has the length $\lambda/2$ at the harmonic frequency and, therefore, acts merely as an additional short circuit across the line at this frequency. An open-circuited line of length $5\lambda/12$ might also be used for stub B.

FIG. 84. Use of stub transmission line to suppress third harmonic.

54. Quarter-wave R-f Lines as Impedance Transformers. A $\lambda/4$ section of line can be used as an impedance-matching or transforming device by virtue of its impedance-inversion properties (Sec. 53). To match an impedance Z_T to another Z_S, a $\lambda/4$ section of transmission line is inserted between the two impedances (Fig. 81b). The characteristic impedance of the matching stub is determined by

$$Z_0 = \sqrt{Z_T Z_S} \tag{156}$$

A perfect transformation is obtained at only the one frequency where the line is exactly $\lambda/4$, and at odd integral multiples of this frequency.

55. Band-pass Characteristics of λ/4 R-f Line Transformers. A line of given physical length has an electrical length of $\lambda/4$ at only one frequency f_0. (Odd integral multiples of f_0 giving odd multiples of $\lambda/4$ have the same transformation properties but are ignored here for practical purposes.) In a system employing a $\lambda/4$ line as an impedance transformer, the impedance match will be less nearly perfect as the frequency deviates from f_0. This point is of interest in connection with modulated signals and band-pass systems. The resulting impedance mismatch at frequencies above and below f_0 is represented for a single $\lambda/4$ section by curve 1 of Fig. 85, which shows the mismatch in terms of magnitude and phase angle for a 10:1 impedance transformation. Frequency is indicated by the ratio f/f_0, and the degree of matching by Z_i/Z_s, where Z_i is the transformed value of Z_T as seen from the input end of the line, and Z_s is the impedance to which Z_T is to be matched.

The degree of matching can be improved over a band of frequencies by using two or more $\lambda/4$ sections (*i.e.*, $\lambda/4$ at f_0) in succession to effect the transformation as shown in Fig. 81. The Z_0 of the successive sections must be selected according to one of several possible schemes. The curves in Fig. 85 show the matching conditions obtained by the use of from two to six $\lambda/4$ sections for an impedance transformation ratio of 10:1 when the successive Z_0's follow an exponential taper law in which the Z_0 of each section is found—in terms of the sending end impedance Z_s—from the relation

$$\log_{10} \frac{Z_{0_n}}{Z_s} = \frac{(2n - 1) \log_{10} M}{2n} = a \log_{10} M \tag{157}$$

where n = number of $\lambda/4$ section counted from sending end
M = over-all transformation ratio, Z_T/Z_s
a = constant found from Table 3
FIG. 85. Degree of wide-band impedance match obtained by use of from one to six $\lambda/4$ transformer sections for 10:1 impedance ratio.

Table 3. Values of a for Use in Eq. (157)

Values of a	Number of sections					
	1	2	3	4	5	6
For Z_{0_1}/Z_s	0.5	0.25	0.1666	0.125	0.1	0.0833
For Z_{0_2}/Z_s	...	0.75	0.5	0.375	0.3	0.25
For Z_{0_3}/Z_s	...	....	0.8333	0.625	0.5	0.4166
For Z_{0_4}/Z_s	...	....	......	0.875	0.7	0.5833
For Z_{0_5}/Z_s	...	....	......	.....	0.9	0.75
For Z_{0_6}/Z_s	...	....	......	.....	...	0.9166

In Fig. 85 the number attached to each curve represents the total number of $\lambda/4$ sections employed. The curves shown are for a transformation ratio of 10:1. For a smaller ratio, they will be flatter; for a larger ratio, they will show larger variations within a given range of frequency. In the design of an exponentially tapered $\lambda/4$ line transformer to match an impedance Z_T to another impedance Z_s, it is convenient to use the last expression in Eq. (157) together with Table 3, which gives values of a for transformers of from one to six sections. The value of f_0 should be chosen in the center of the frequency band to be covered by the system, and the physical length of each section of line should correspond to an electrical length of $\lambda/4$ at the frequency f_0.

56. Properties of Half-wave R-f Lines. Dissipationless half-wave lines and lines whose lengths are integral multiples of $\lambda/2$ have input impedance Z_i exactly equal to the terminating impedance Z_T, independent of the Z_0 of the line.

$$Z_i = Z_T \qquad \text{ohms} \tag{158}$$

57. Dimensional Data for R-f Stub Lines. The range of frequencies in which the use of stub or transformer lines is practical is limited at the lower extreme by the physical dimensions of the line structure required at the longer wavelengths, and at the upper extreme by the relative inefficiency of conductor-type lines as compared to wave guides.

To determine the physical length of a stub line, it is necessary to take into account the actual velocity of propagation along the line. The following relations are useful in determining physical lengths of lines for this purpose:

$$\lambda/4 \text{ length} = \frac{75}{f_{Mc}} \times \text{V.F. meters} = \frac{246.1}{f_{Mc}} \times \text{V.F. ft} = \frac{2{,}952.8}{f_{Mc}} \times \text{V.F. in.}$$

$$\lambda/2 \text{ length} = \frac{150}{f_{Mc}} \times \text{V.F. meters} = \frac{492.1}{f_{Mc}} \times \text{V.F. ft} = \frac{5{,}905.5}{f_{Mc}} \times \text{V.F. in.}$$

$$\lambda \text{ length} = \frac{300}{f_{Mc}} \times \text{V.F. meters} = \frac{984.3}{f_{Mc}} \times \text{V.F. ft} = \frac{11{,}811}{f_{Mc}} \times \text{V.F. in.}$$

where f_{Mc} = frequency, Mc
λ = 1 electrical wavelength
V.F. = velocity factor expressed as a fraction of the speed of light

The value of V.F. must be determined for the line to be used. Representative values for common types of lines are

V.F. = 0.92 to 0.99 for open-wire air dielectric lines
V.F. = 0.79 to 0.99 for beaded coaxial lines with air dielectric
V.F. = 0.6 to 0.82 for solid dielectric lines

58. Voltage and Power Ratings of R-f Lines. In selecting a transmission line for a transmitter application, consideration must be given to voltage flashover and power limitations. Maximum voltage is limited by conductor spacing, insulation and the corona formation point, and maximum power by line losses and conductor current-carrying capacity. Voltage, current, and power are interrelated in the case of a line operated with matched terminal impedances so that standing waves do not exist:

$$P = \frac{E^2}{Z_0} = I^2 Z_0 \qquad \text{watts} \tag{159}$$

where P = power carried by line, watts
E = rms voltage between conductors, volts
I = rms current in each conductor, amp
Z_0 = characteristic impedance of line, ohms

The corresponding relations for a line with standing waves are

$$E_{max} = \sqrt{P \times Z_0 \times \text{SWR}} \tag{160}$$

$$I_{max} = \sqrt{\frac{P \times \text{SWR}}{Z_0}} \tag{161}$$

where SWR is the standing-wave ratio as defined in Eq. (124).

Corona occurs when the voltage gradient at some point in the line exceeds the breakdown potential of air (or gas in the case of gas-filled lines). Corona is not necessarily accompanied by flashover but is objectionable because the energy dissipated represents an increase in the line losses. Chemical by-products of sustained corona discharges may also tend to deteriorate the line insulation. The critical surface gradient at which corona begins to form in air at 25°C and atmospheric pressure depends upon the conductor size. For conductors of No. 0 B&S and larger, it is about 40,000 volts per cm peak, or 28,000 volts per cm rms. For smaller conductors, it is approximately $(40{,}000 + N \times 1{,}670)$ volts per cm peak, or $(28{,}000 + N \times 1{,}180)$ volts per cm rms, where N is the B&S gage size of the wire. Maximum gradients in r-f lines occur at the surfaces of the conductors in open-wire lines, and at the surface of the inner conductor in coaxial lines. They may be evaluated by Eqs. (145) and (149). All such computations must be considered as approximations, but they are sufficiently accurate for engineering purposes if adequate safety factors are allowed.

WAVE FILTERS

59. Wave filters are forms of artificial lines, such as those of Fig. 86, purposely designed to transmit efficiently current in a desired band of frequencies and more or less completely to suppress all other frequencies. The boundary frequencies between transmission bands and attenuation bands are called *cutoff frequencies*.

The following brief discussion of wave-filter design is intended to serve as a guide to the design of simple filters for use where the requirements are not very severe. For complete information concerning the design of filters to meet more exacting specifications, the references listed in the bibliography at the end of this chapter should be consulted.

FIG. 86. Basic wave-filter circuits.

Filters are divided into four classes, according to the frequency bands which they are intended to transmit: *low pass, high pass, band pass,* and *band elimination.*

60. Losses in Filters, and Effects of Dissipation. The elements of ideal wave filters are always pure reactances; practically, however, some dissipation must always be tolerated owing to the resistance of coils and capacitors, but this is made as small as possible by employing high-Q elements.

The terminating impedances of a filter are usually resistances equal in value to the image impedances of the filter. Then the loss within the transmitted bands (except near the cutoff frequency) is mainly due to dissipation in the elements and is usually small. In the vicinity of cutoff and the point of maximum attenuation, the total insertion loss of a filter involves the reflection and interaction losses as well as the attenuation. The loss elsewhere in the attenuated bands is very nearly the sum of the attenuation constants of the various sections, minus a gain of approximately 6 db which is due to reflections resulting from impedance mismatches occurring in these regions. Methods for the exact calculation of filter losses are beyond the scope of this handbook but are available in the published works of Zobel, Johnson, and Shea.

61. The Basic Filter Section. The basis of filter design is the full L section, consisting of a series element Z_1 and a shunt element Z_2 as shown at a in Fig. 87. The relation of such a section to an infinite line is also indicated. In a wave filter, where the

number of sections is finite and small instead of infinite, symmetrical sections are used. These are either T or π networks as shown at *b* and *c* in Fig. 87. The T section may be considered as being cut from the infinite line (Fig. 87*a*) at the mid-points (*a–a*) of two consecutive series elements Z_1 and is said to be "mid-series terminated." The π section may be considered as being cut at the midpoints (*b–b*) of two consecutive shunt elements and is said to be "mid-shunt terminated." (To form a mid-shunt termination, each full-shunt element is replaced by an equivalent two impedances
FIG. 87. Equivalence of T and π networks.

in parallel, each of value $2Z_2$.) Either a T or π section may be divided into pairs of equivalent half sections as shown at *d* and *e* in Fig. 87.

62. Types of Sections. 1. *Constant-K Sections.* The simplest and most common type of filter section is that in which the impedances Z_1 and Z_2 are so related that their product is a constant

$$Z_1 \times Z_2 = K^2$$

at all frequencies. From this it derives its name "constant-K" section. The configuration and circuit constants of the four classes of constant-K sections are shown in the filter-design formulas in Sec. 66. The image impedance of mid-series and mid-shunt terminated constant-K sections within the transmission bands are functions of frequency, but each approaches the value K at some frequency within the band. The value K is therefore taken as the nominal resistance of the constant-K section for design purposes. If a constant-K section is used with one or both of its terminals

connected to a pure resistance of value $R = K$, the impedances will be mismatched for all frequencies within the transmitted band except one, and the actual insertion or transmission loss of the filter will be increased by reflection losses at the terminations. This causes an even more gradual cutoff for the constant-K section than its attenuation curve would indicate.

2. *m-derived Sections.* In many filters, a sharper cutoff than that given by a constant-K type of structure is required. Such a characteristic may be realized in the so-called *m-derived section*, which is due to Otto J. Zobel.[1] This type of section is derived from the constant-K section as a prototype but is made to have sharper cutoff than the prototype by the addition of impedance elements in either the shunt or series arms so that infinite attenuation occurs at some frequency beyond cutoff. Each impedance of the m-type section is related to those of the constant-K section by a factor which is a function of a constant m. The latter is in turn a function of the ratio between the frequency of infinite attenuation and the cutoff frequency and may have any value between 0 and plus 1. The sharpness of cutoff increases as m approaches 0. This effect is illustrated in Fig. 88 for various values of m. It will be noted that, when m is equal to 1, the structure is identical with the constant-K structure. Also, from Fig. 88, it appears that from the viewpoint of obtaining a uniform degree of attenuation throughout the attenuated band the combination of a constant-K section ($m = 1$) (having gradual cutoff but large attenuation remote from cutoff) with one having a small value of m and sharp cutoff ($m = 0.3$, for example) would be desirable. This principle is valuable in the design of composite filters.
FIG. 88. Effect of m on sharpness of cutoff in a low-pass filter structure.

3. *Shunt-derived and Series-derived m Sections.* Two forms of m-derived sections exist; if the extra impedance is added to the shunt arm, the section is called *series derived*, while, if it is added to the series arm, the section is called *shunt derived*. (See illustrations of derived sections under Filter-design Formulas, Sec. 66.)

63. Assembly of Sections into Filters. A filter may consist of any number of sections from a single one-half section to five or six full sections, depending on the amount of attenuation of unwanted frequencies required. The *amount* of attenuation in the rejected band depends upon the number of filter sections used, and the *shape* of the transmission curve depends upon the types of sections employed.

64. One-half- and One-section Filters. If a half section or one full section is used alone as a filter and the requirements regarding the cutoff are not too sharp, an m-derived section is usually preferable, with $m = 0.6$. This will provide the best impedance match with resistance termination. Either of the structures shown in Fig. 89 is suitable for use with terminations of resistance R.

65. Multisection Filters. Filters having more than one section are of two types:

A *uniform* filter is one in which all sections are identical with the exception of the end sections. The latter are ordinarily half sections suitable for connecting the filter to its terminating resistances.

A *composite* filter is one made up of two or more sections having different characteristics, each of which is designed to contribute some special property to the characteristic of the filter as a whole. For example, one section which has sharp cutoff but a diminishing attenuation beyond cutoff may be combined with another section having a gradual cutoff and increasing attenuation beyond, as shown at I and II in Fig. 90. The resulting composite structure will then have both sharp cutoff and high attenuation beyond, as shown at III. In general, constant-K sections have gradual cutoffs

[1] *Bell System Tech. J.*, January, 1923.

FIG. 89. Half- and full-section filters.

with increasing attenuation beyond, while m sections with small values of m have the sharpest cutoff characteristics. Still other types of sections may be added to match impedances at the junctions of the filter and its terminating resistances, or to further alter the transmission characteristics.

In a composite filter it is essential that the image impedances be matched at each junction of the component sections, to avoid reflection losses which would impair the transmission curve of the filter. Likewise, the end terminations of the filter should as nearly as possible match the terminating resistances. One of the principal advantages of the m-type structure is that its image impedances can be made identical with other m-type sections or with constant-K sections; or they can be made to approximate resistances over the transmission band for terminating purposes. A complete analysis of the impedance conditions within a wave filter is not possible in the limited space available here but may be found in the references listed at the end of this chapter. The following will suffice as working rules in designing simple filters for ordinary requirements:
FIG. 90. Transmission curves for composite low-pass filter.

End Terminations. *Resistance.* A mid-shunt termination of a series-derived m-type section or half section, or a mid-series termination of a shunt-derived section or half section, with $m = 0.6$ in either case.

For Parallel or Series Connection with Other Filters. An 0.8 series constant-K section or half section (*i.e.*, one terminated in a series arm equal to 0.8 of a full series arm, Z_1).

Here, as well as in the two preceding paragraphs, the image impedance of the internal section next to the end section in either case must match the image impedance at the inner terminals of the latter, in accordance with the following.

Internal Junctions. The following terminations of the types of filter sections for which formulas are given in Sec. 66 may be joined together without impedance mismatches at the junction points:

Mid-series termination of constant-K type to mid-series termination of series-derived m type.

Mid-shunt termination of constant-K type to mid-shunt termination of shunt-derived m type.

Mid-series termination of constant-K, series-derived m type or shunt-derived m type to mid-series termination of another section of the same type.

Mid-shunt termination of constant-K, series-derived m type or shunt-derived m type to mid-shunt termination of another section of the same type.

NOTE: In the latter two cases, the values of m in the two sections to be joined, if they are of the m type, may be, and frequently are, different. Both sections must be of the same type and termination, however.

66. Filter-design Formulas. Formulas for calculating the capacitances and inductances of constant-K, series-derived m-type and shunt-derived m-type basic sections are given on pages 5-83 and 5-84. These are expressed in terms of R, the terminating resistances, the factor m, and the values of f_c, the cutoff frequency, and other critical frequencies. These factors must be predetermined on the basis of the filter requirements and the considerations outlined above.

Examples of Filter Design: 1. *Single-section Filter.* Required: High-pass single-section filter to be connected between resistance terminations of R = 1,000 ohms, with a cutoff frequency of 1,000 cycles and maximum attenuation occurring at 800 cycles.

To secure the attenuation peak at 800 cycles, an m-type filter section is required. Either the shunt- or series-derived type may be used. Choosing the latter, we have from the filter formulas II (b), Sec. 65,

$$
\begin{aligned}
f_1 &= 1{,}000 \text{ cycles} \\
f_{1\infty} &= 800 \text{ cycles} \\
R &= 1{,}000 \text{ ohms} \\
m &= 0.6 \\
C_1 &= 0.1325 \times 10^{-6} \text{ farad} \\
L_2 &= 0.1325 \text{ henry} \\
C_2 &= 0.298 \times 10^{-6} \text{ farad}
\end{aligned}
$$

From the considerations involving impedance matching at the end terminals, a mid-shunt termination facing each resistance termination is seen to be desirable for a series-derived section. Hence the structure of Fig. 89f is indicated. One full-series element (C_1) will be required, with a double-impedance shunt arm ($2L_2 + C_2/2$) at each end. The completed filter will then be as shown in Fig. 91.
FIG. 91. Example of single-section filter.

2. *Multisection Composite Filter.* Required: Low-pass filter to be connected between resistance terminations of R = 600 ohms, with sharp cutoff at 1,000 cycles and high attenuation beyond.

There is no unique solution or "best" filter design for this problem. A large number of filters might be designed to meet these requirements, each of which would serve as well as any of the others. The relative merits of different designs will depend upon their economy of coils and capacitors in accomplishing the required results. One suitable design is shown here:

Let the input-end section be a half-section mid-series-derived m type, with its mid-shunt

termination facing the input to match impedances at that point. Let $m = 0.4$ for this half section to give a sharp cutoff.

This will be followed by a symmetrical full section of the series-derived m type, mid-series terminated, with $m = 0.75$; then a half section of the constant-K type with mid-series termination facing the full section and mid-shunt termination facing the end-terminating half section, which will be shunt-derived m type, with $m = 0.6$. The latter will have a
FIG. 92. Low-pass filter for use between 600 ohms with sharp cutoff at 1,000 cps.
FIG. 93. Final filter as designed by Fig. 92.

mid-shunt termination facing the constant-K half section and a mid-series termination facing the output termination.

CHAPTER 6

WAVE GUIDES AND CAVITY RESONATORS

By Harald Schutz[1]

1. Relationship between Wave Guides and Transmission Lines. A transmission line may be defined as a system of material boundaries forming a continuous path from one place to another and capable of directing energy along this path. The electromagnetic energy is carried along a transmission line in the form of guided electromagnetic waves. Transmission-line theory may be developed in terms of these traveling waves which propagate in either direction along the line.

Wave guides are included as transmission lines by the above definition. This is justified because many wave-guide phenomena are readily interpreted in terms of the
Fig. 1. Electric and magnetic fields for principal mode of propagation in coaxial line.

traveling-wave theory of transmission lines, and it is possible to draw equivalent transmission-line circuits for many wave-guide structures. Certain modifications to ordinary line theory are required for wave-guide transmission circuits. To determine these modifications, it is necessary to examine the nature of traveling waves on transmission lines.

A transmission line at ordinary radio frequencies consists of two or more separated conductors. When the line is energized, currents flow in these conductors and voltages exist between conductors. Electric and magnetic fields are found in the insulating medium separating the conductors. An example is the coaxial line shown in Fig. 1. The electric lines of force are shown as solid lines, and the magnetic lines of force as broken lines. The electric and magnetic lines of force are at right angles to each other, as is usually characteristic of electromagnetic waves. In the example, the electric and magnetic lines of force are also everywhere transverse to the direction of energy propagation, which is along the axis of the conductors. For this reason, the wave shown is called a *transverse electromagnetic wave*, abbreviated *TEM*.

TEM waves are used in all conventional transmission lines. If there are only two conductors, only one *TEM* wave is possible. If there are more than two conductors, more than one *TEM* wave may exist.[2]

[1] The Martin Co. Several sections of this chapter were written by Theodore Moreno and appeared in the Fourth Edition of this handbook, and the chapter as a whole leans heavily on his work for that edition.

[2] For example, in a two-wire overground transmission line, there is one wave in which the current

There may exist on a transmission line, in addition to the limited number of *TEM* waves, an infinite number of other types of waves, or higher modes of transmission. Each of these other modes has its own distinctive configuration of electric and magnetic fields. For a coaxial line, a few of the higher modes are shown in Fig. 2. The
FIG. 2. Field configurations for some of the higher modes on coaxial line.

TEM wave, also called the *principal mode,* is distinguished from these higher modes in a number of ways. For example:

1. The transmission line acts as a high-pass filter for the higher modes, and the line will carry energy only if the frequency is above a cutoff frequency. This cutoff frequency is in general different for each higher mode. The higher modes may be excited at frequencies lower than their cutoff frequencies, but their strength will diminish very rapidly with increasing distance from the point of excitation.
2. The wavelength measured on the transmission line will be greater for the higher modes than for the principal mode.
3. The characteristic impedance and propagation constant of the line for the higher modes will differ from the values for the principal mode. The characteristic impedance is harder to define for the higher modes, as there no longer exists a unique value of voltage between conductors.

A transmission line requires two separated conductors to support a principal mode, but higher modes can carry energy on transmission lines that have only one conductor. For example, the coaxial line modes shown in Fig. 2 will reduce to the circular waveguide modes shown in Fig. 6 as the diameter of the center conductor is reduced to zero.

A wave guide is a transmission line not operating in a *TEM* mode. Most wave guides are incapable of supporting a *TEM* wave. They must therefore have less than two separated conductors. Normally a wave guide consists of a hollow conducting cylinder, of arbitrary cross section, with the electromagnetic fields confined to the inside of the cylinder. A dielectric rod may also act as a wave guide in the absence of any conductor.

Because of the phenomenon of cutoff that is peculiar to wave guides, the required dimensions of a wave guide for energy transmission are larger at lower frequencies. For most applications, wave guides are impractically large and bulky at frequencies below 1,000 to 2,000 Mc. On the other hand, conventional transmission lines, such as coaxial lines, must be restricted in size to keep the higher modes below cutoff[1] and become impractically small at frequencies much higher than 10,000 Mc. In the region between 1,000 and 10,000 Mc, both wave guides and coaxial lines are extensively used. Coaxial lines are smaller and lighter and, if cables are used, more flexible. On the other hand, wave guides offer lower attenuation, greater power-carrying capacity, and mechanical simplicity. A rectangular wave guide has a practical fre-

flows down one wire and returns in the other, and a second wave in which the current flows down both wires and returns through the ground.

[1] In a coaxial line, the cutoff wavelength of the first of the higher modes is given approximately by

$$\lambda_c \doteq \sqrt{\epsilon}\,\pi(b + a)$$

where b and a are the outer and inner radii of the line and ϵ is the dielectric constant of the medium separating the conductors.

quency range of less than two to one, while the band width of a coaxial line is much greater. A comparison of a typical wave guide, air dielectric coaxial line, and flexible cable is given in Table 1 for a frequency of 5,000 Mc.[1]

Table 1. Comparison of Transmission Lines for 5,000 Mc

Type of line	Rectangular wave guide	Rigid coaxial line	Flexible cable
Army-Navy type No.	RG-49/U	RG-76/U	RG-9B/U
Outside dimensions	2 × 1 in.	⅝ in. diam	0.425 in. diam
Conductor material	Brass	Brass	Inner conductor, 7/21 AWG silvered copper Outer conductor, double braid, inner silvered copper, outer copper
Surface finish	Silver	Silver	Silver
Dielectric	Air	Air	Polyethylene
Weight, lb per ft	1.40	0.292	0.158
Attenuation, db per ft	0.011	0.035	0.23
Recommended power rating	1.2 Mw	0.3 Mw	4,000 volts rms max, 66 watts continuous

2. Characteristics of Wave-guide Modes.[2] The higher modes which may carry energy in uniform wave guides with homogeneous dielectric are divisible into two classes: *TE* and *TM* modes, each infinite in number for all wave guides.

TE (Transverse Electric) Modes. The electric field is everywhere transverse to the direction of energy propagation, which is the direction of the guide axis. The magnetic field has transverse components, but in addition has components parallel to the axis. These modes are also called *H* waves
FIG. 3. Dominant mode, $TE_{1,0}$, in rectangular wave guide, showing electric and magnetic fields and conduction currents in walls.

TM (Transverse Magnetic) Modes. The magnetic field is everywhere transverse to the guide axis. The electric field has transverse components, but in addition has components parallel to the axis. These modes are also called *E* waves.

It is customary to identify individual modes by an additional subscript notation, the rules of which depend upon the guide configuration. For circular and rectangular cross sections, these rules are discussed in the following paragraphs.

For any wave guide, the mode of transmission that has the lowest cutoff frequency is called the *dominant mode.*

Rectangular Wave Guides.[3] Individual modes in rectangular wave guides are identified by giving the class of the transmission mode, followed by two numerical subscripts. For example, the dominant mode in rectangular wave guide, illustrated in Fig. 3, is the $TE_{1,0}$ mode. The first and second subscripts indicate the number of

[3] Chu and Barrow, *loc. cit.*

half-period variations in transverse field intensity along the larger and smaller cross-section dimensions, denoted by a and b, respectively. A few of the higher modes of transmission are illustrated in Fig. 4. The $TE_{1,0}$ mode in rectangular wave guide deserves special consideration, because it is by far the most widely used mode of transmission in practical wave guides. Also, a simple physical picture of the wave structure is possible, from which many of the basic formulas that apply to all types of wave guides may be developed.

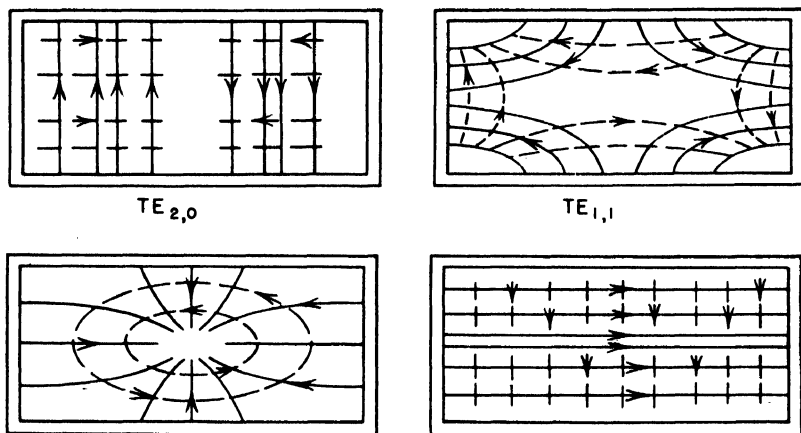
The fields inside the wave guide may be considered to result from the addition of two plane waves, whose electric fields are parallel to the side walls of the guide.[1]


FIG. 4. Some of the higher modes of transmission in rectangular wave guide.

Each of these waves advances at an angle with respect to the axis of the guide, and each is the reflection of the other from the side walls of the guide. For the tangential electric field to be zero at the conducting side walls, the two plane waves must be out of phase at the walls; *i.e.*, the positive crest of one wave coincides with the negative crest of the other. This is illustrated in Fig. 5. Maximum electric field intensities are found at the center of the guide, where the two traveling waves are in phase and reinforce each other.

When the frequency is much higher than the cutoff frequency, the two component plane waves travel nearly parallel to the axis of the guide. As the frequency decreases toward cutoff, the angle between the guide axis and the direction of propagation of the component waves increases. At cutoff, this angle reaches 90 deg, and the two component waves are reflected back and forth between the side walls with no propagation of energy down the guide. At cutoff, the distance between the side walls is one-half a free-space wavelength. For the $TE_{1,0}$ mode in rectangular wave guide, the cutoff wavelength λ_c is related to the larger dimension of the wave guide a by

$$\lambda_c = 2a \tag{1}$$

The distance between positive and negative crests measured along the axis of the guide is seen by Fig. 5 to be greater than the distance between positive and negative crests of the component plane waves. This leads to the very important conclusion that the apparent wavelength in a wave guide, which is the distance between surfaces of equivalent phase, is greater than the free-space wavelength at the same frequency. If a wave guide is used as a Lecher wire system to measure wavelength, this correction must be made.

[1] Page, L., and N. I. Adams, Jr., Electromagnetic Waves in Conducting Tubes, *Phys. Rev.*, **52** (18), Sept. 15, 1937. Also see H. H. Skilling, Physical Behavior of Wave Guides, *Electronics*, **16** (3), 76, March, 1943, which gives a less mathematical but more graphical development.

More complex modes in rectangular wave guide may be constructed by the superposition of more than two plane waves. The method is applicable, in fact, to wave guides of any cross section, although in general an infinite number of plane waves are required and the calculation becomes tedious.[1]
FIG. 5. Construction of the dominant mode in rectangular wave guide by the superposition of two plane waves traveling at an angle with respect to the guide walls.

3. Phase and Group Velocity. The component plane waves, which add to give the fields inside the guide, travel at the speed of light (3×10^{10} cm per sec). Since the wave-guide wavelength λ_g is greater than the wavelength of the component waves λ, this gives rise to a *phase velocity* in the wave guide v_p which exceeds the velocity of light c by the ratio v_p/c. The rate of energy propagation down the guide is not equal to the phase velocity, however, but is instead less than the velocity of light, because the component waves which carry the energy travel at an angle with respect to the guide axis. The rate of energy propagation along the axis is equal to the projection

[1] Mackeown, S. S., and J. W. Miles, The Plane Wave Resolution of Guided Waves, *Proc. IRE*, **33** (11), 805, November, 1945.

upon the axis of the velocity vector of the component waves. This rate of energy propagation is known as the *group velocity* v_g. The group velocity and the phase velocity are related to the velocity of light by

$$v_p v_g = c^2 \tag{2}$$

This relationship holds for any mode in any air-filled wave guide.

† For all sizes: Min outer radius 1/64 in. Max outer radius 1/32 in.

The relationship between free-space wavelength λ, wave-guide wavelength λ_g, and cutoff wavelength λ_c for any mode in any air-filled wave guide is given by

$$\lambda_g = \frac{\lambda}{\sqrt{1 - (\lambda/\lambda_c)^2}} \tag{3}$$

For the important $TE_{1,0}$ mode in rectangular wave guide, the cutoff wavelength is

given by Eq. (1), and Eq. (3) reduces to

$$\lambda_g = \frac{\lambda}{\sqrt{1 - (\lambda/2a)^2}} \tag{4}$$

For all TE and TM modes in rectangular wave guide, the cutoff wavelength is given by

$$\lambda_c = \frac{2}{\sqrt{\left(\frac{m}{a}\right)^2 + \left(\frac{n}{b}\right)^2}} \tag{5}$$

In Eq. (5), m and n are the subscripts denoting the particular mode under consideration (*e.g.*, $TE_{m,n}$), and also indicate the number of half-period variations in transverse field intensity along the a and b cross-section dimensions of the guide, respectively.

If a rectangular guide is to be above cutoff for the dominant $TE_{1,0}$ mode, but below cutoff for all other modes,

$$a > \frac{\lambda}{2} < \lambda$$

$$b < \frac{\lambda}{2}$$

Various standard sizes of rectangular wave guide for broad-band use have been recommended by the EIA Subcommittee on Microwave Transmission Lines. These are given in Table 2, taken from *Electronics*, p. 111, June, 1949, along with the frequency range for which each of the guides is recommended.

4. Circular Wave Guides.[1] A number of possible modes of transmission in circular wave guides are shown in Fig. 6. For any mode of transmission in a circular wave guide, the transverse fields may be resolved into two components: tangential and radial. Both of these components vary periodically along a circular path concentric with the wall, and both vary in a manner related to a Bessel function of the first kind of order m along a radius. Any particular mode is identified by the notation $TE_{m,n}$ or $TM_{m,n}$, where m is the total number of full-period variations of either component of field along a circular path concentric with the wall, and n is one more than the total number of reversals of sign of either component of field along a radial path.
Fig. 6. Some transmission modes in circular wave guides.

[1] Southworth, *loc. cit.* Carson, Mead, and Schelkunoff, *loc. cit.* Barrow, *loc. cit.*

The dominant mode in circular wave guide, that with the longest cutoff wavelength, is the $TE_{1,1}$ mode, which corresponds to the $TE_{1,0}$ mode in rectangular guide. This mode is shown in Fig. 6. Another mode that is of considerable interest is the $TM_{0,1}$, or circular magnetic mode. This is the lowest mode with circular symmetry. A mode of considerable theoretical interest is the $TE_{0,1}$ mode, which has anomalous attenuation characteristics discussed below.

The cutoff wavelength for all modes in circular wave guide depends upon the ratio of diameter to wavelength. For the $TE_{m,n}$ modes, the cutoff wavelength is given by

$$\lambda_c = \frac{2\pi a}{u_{m,n}'} \tag{6}$$

where a is the inner radius of the guide. The constant $u_{m,n}'$ is the nth root of the equation $J_m'(u) = 0$, where the prime denotes differentiation. Some of the lower values of $u_{m,n}'$ are

$u_{01}' = 3.832$	$u_{02}' = 7.016$	
$u_{11}' = 1.841$	$u_{12}' = 5.332$	$u_{13}' = 8.536$
$u_{21}' = 3.054$	$u_{22}' = 6.706$	
$u_{31}' = 4.201$	$u_{32}' = 8.016$	

For the $TM_{m,n}$ modes, the cutoff wavelength is given by

$$\lambda_c = \frac{2\pi a}{u_{m,n}} \tag{7}$$

where a is the inner radius of the guide and $u_{m,n}$ is the nth root of the equation $J_m(u) = 0$. Some of the lower values of $u_{m,n}$ are

$u_{01} = 2.405$	$u_{02} = 5.520$	$u_{03} = 8.654$
$u_{11} = 3.832$	$u_{12} = 7.016$	
$u_{21} = 5.136$	$u_{22} = 8.417$	
$u_{31} = 6.380$		

The cutoff frequency of the $TM_{0,1}$ mode is only 30 per cent higher than the cutoff frequency of the $TE_{1,1}$ mode, and the frequency range over which only the dominant $TE_{1,1}$ mode is above cutoff is correspondingly limited. To operate a wave guide over a wider frequency band in any mode of transmission, the means of excitation must be chosen so as to excite only the desired mode, or else mode dampers must be employed. These mode dampers may consist of grids of wire designed to short-circuit the undesired modes while leaving the desired mode unaffected. Methods of selective mode excitation are discussed later.

Fig. 7. Modes in elliptical guide and corresponding modes in circular wave guide.

5. Elliptical Wave Guides. The inevitable deformations encountered in circular wave guides result in an equivalent ellipticity, and the properties of elliptical

wave guides are, therefore, of practical interest.[1] A few of the possible modes in elliptical wave guide are shown in Fig. 7, along with the corresponding modes in circular wave guide. In general, if a round wave guide is deformed, each mode will split into two modes of orthogonal polarization with different phase velocities and different attenuations. Only those modes with circular symmetry (*e.g.*, $TE_{0,1}$ and $TM_{0,1}$) do not have this instability.

Other cross sections for wave guides have been the subject of some theoretical investigation but have found limited practical application to date. One of the more interesting designs is the H-shaped cross section[2] shown in Fig. 8. A wave guide of this design has over-all dimensions that are relatively small compared to the cutoff wavelength. Also, the frequency separation between cutoff for the dominant mode of transmission and that for the higher mode is comparatively large.

6. Characteristic Impedance of Wave Guides. The characteristic impedance of ordinary two-wire transmission lines may be defined as the input impedance to a line of infinite length and may be expressed as the ratio of voltage E between conductors to the current I flowing in each conductor ($Z_0 = E/I$) for a transmission line free from standing waves. It is not possible to extend this definition to wave guides, because there are no separated conductors between which a unique value of voltage exists. In an ordinary transmission line, it is possible also to define characteristic impedance in terms of the net power flow W into a matched line ($Z_0 = W/I^2$ or $Z_0 = E^2/W$). The net power flow into an infinite wave guide may be calculated when the field strengths at a cross section are given. If a certain logical value of voltage or current is then chosen as reference, it is possible to define a characteristic impedance of the guide in terms of the reference voltage or current and the power input. The actual numerical value of the impedance will depend upon precisely what voltage or current was chosen for reference. The ratio between values of characteristic impedance obtained by different choices of reference voltage or current will be numerically constant, however, and independent of changing frequency or guide dimensions.

FIG. 8. H-shaped wave guide.

For example, with the $TE_{1,0}$ mode in rectangular wave guide, if the maximum voltage between top and bottom guide faces is chosen as the reference voltage, the characteristic impedance of the guide becomes[3]

$$Z_0 = 377 \frac{\lambda_g}{\lambda} \frac{2b}{a} \tag{8}$$

If the total axial current in the top or bottom face is chosen as the reference current, the characteristic impedance will differ from the above expression only by the numerical factor of $\pi^2/16$.

For many applications, the numerical value of the characteristic impedance is of little importance, as the impedances of the associated elements in the circuit may be normalized with respect to the guide impedance. It is, however, important to adjust impedances of various transmission-line and wave-guide components to match them for most efficient power transmission and minimum reflection at the junctions. Transformers must be designed and adjusted. They take many physical shapes. A number of impedance and admittance charts have been devised, and some of them have found widespread application.

[3] Schelkunoff, S. A., Impedance Concept in Wave Guides, *Quart. Applied Math.*, **2** (1), 1–15, April 1944.
The relative admittance at any point z of a transmission line can be related to that at point z_0 by

$$Y'(z) = \frac{j + Y'(z_0) \cot k(z_0 - z)}{\cot k(z_0 - z) + jY'(z_0)} \tag{8a}$$

where $k = 2\pi/\lambda_g$.

Equation (8a) can be rewritten as a fundamental impedance relation

$$Z'(z) = \frac{j + Z'(z_0) \cot k(z_0 - z)}{\cot k(z_0 - z) + jZ'(z_0)} \tag{8b}$$

The similarity between Eqs. (8a) and (8b) indicates the validity of a duality principle for transmission-line equations.

P. H. Smith of the Bell Telephone Laboratories developed the most frequently used system of transmission-line charts for microwave use.[1] In recent years graphical methods of presenting impedance and admittance relations have been developed further. Examples are the hyperbolic protractor of Deschamps[2] and the work of Wheeler.[3]

7. Power-carrying Capacity of Wave Guides. The power-carrying capacity depends upon the maximum electric field strength that can exist without breakdown. Experimental evidence indicates that at microwave frequencies, this maximum field strength is 30,000 volts per cm under standard sea-level conditions of temperature, pressure, and humidity.

For rectangular wave guide operating in the $TE_{1,0}$ mode, the maximum power P is related to the maximum field strength E_{max} by

$$\frac{P}{E_{max}^2} = 6.63 \times 10^{-4} ab \left(\frac{\lambda}{\lambda_g}\right) \tag{9}$$

If E_{max} is given in volts per centimeter, the inside dimensions of the guide, a and b, should be given in centimeters for the power to be in watts. The free-space wavelength is λ, the guide wavelength λ_g. The maximum field intensity occurs parallel to the narrower dimension of the guide, midway between the side walls, and is independent of the distance from the wide faces of the guide.

For circular wave guides operating in the dominant $TE_{1,1}$ mode the relation between maximum power and maximum field strength is

$$\frac{P}{E_{max}^2} = 1.99 \times 10^{-3} a^2 \left(\frac{\lambda}{\lambda_g}\right) \tag{10}$$

where a = radius of guide, cm
λ = free-space wavelength
λ_g = wave-guide wavelength

Maximum field strength is at the center of the guide.

For the $TM_{0,1}$ mode in circular wave guide, there are two cases:

Case 1—$a/\lambda < 0.761$:

$$\frac{P}{E_{max}^2} = 7.69 \times 10^{-3} \frac{a^4}{\lambda^2} \left(\frac{\lambda}{\lambda_g}\right) \tag{11}$$

The maximum field intensity is at the center of the guide.

[1] Smith, P. H., Transmission Line Calculator, *Electronics*, January, 1939, p. 29; Improved Transmission Line Calculator, *Electronics*, January, 1944, p. 130.

[2] Deschamps, G., A New Chart for the Solution of Transmission Line and Polarization Problems, *Trans. IRE*, **MTT-1,** March, 1953.

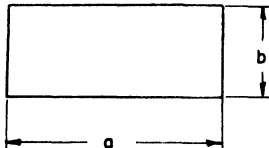
[3] Wheeler, H. A., Geometric Relations in a Circle Diagram of Transmission-line Impedance, Wheeler Monographs, 4, July, 1948.

Case 2—$a/\lambda > 0.761$:

$$\frac{P}{E_{\max}^2} = 3.33 \times 10^{-3} a^2 \left(\frac{\lambda_g}{\lambda}\right) \tag{12}$$

The maximum field intensity is at a radius of $0.765a$ and is independent of angle. All dimensions in the above formulas should be given in centimeters for the power to be in watts.

The power-carrying capacity of a wave guide will diminish with altitude approximately as shown in Fig. 9.
Fig. 9. Decrease in power-handling capacity at increasing altitude.

8. Attenuation in Wave Guides. At frequencies below cutoff, the attenuation in any wave guide is very rapid, even for perfectly conducting walls, as the guide is unable to support traveling waves. At frequencies higher than cutoff, the guide can support traveling waves, but they are attenuated because of losses in the conducting walls and in the dielectric that fills the guide. For air-filled guides, the dielectric losses are usually negligible, but if dielectrics other than air are used, the dielectric losses are often greater than the conductor losses.


9. Conductor Losses. The conductor losses in a wave guide are governed in part by skin-depth considerations, as the current that flows in the guide walls is concentrated near the inner surface. The attenuation will vary as the square root of the resistivity of the material which forms the conducting walls.

As the frequency increases beyond the cutoff frequency, the attenuation drops rapidly from a very high value at cutoff to a broad minimum, and then increases slowly with increasing frequency. This is the behavior for all modes in all wave guides except the family of circular electric modes (*e.g.*, $TE_{0,1}$) in circular wave guide. These modes have anomalous characteristics that are discussed in a succeeding paragraph.

The formulas that are given below for wave-guide attenuation indicate that the attenuation approaches infinity as the frequency approaches cutoff. However, the approximations under which these equations were developed are not valid in the region immediately adjacent to cutoff, for there is actually a smooth transition between the approximate results that are given below for the above-cutoff and below-cutoff regions.

10. Attenuation in Rectangular Wave Guides. Formulas for the attenuation in rectangular, copper, air-filled wave guide are given in Table 3. The inner dimensions of the guide, a and b, are in inches. The larger dimension is a. If some metal other than copper is used as a conductor, the attenuation given by Table 3 should be multiplied by the square root of the resistivity of the metal compared to that of copper.

Table 3. Attenuation in Rectangular, Copper, Air-filled Wave Guides

f = frequency
f_c = cutoff frequency
a and b in inches

Mode	α, Db/Ft
$TE_{1,1}$	$\frac{0.01107}{a^{3/2}}\left[\frac{\frac{1}{2}\frac{a}{b}\left(\frac{f}{f_c}\right)^{3/2}+\left(\frac{f}{f_c}\right)^{-1/2}}{\sqrt{\left(\frac{f}{f_c}\right)^2-1}}\right]$
$TE_{2,0}$	$\frac{0.01565}{a^{3/2}}\left[\frac{\frac{1}{2}\frac{a}{b}\left(\frac{f}{f_c}\right)^{3/2}+\left(\frac{f}{f_c}\right)^{-1/2}}{\sqrt{\left(\frac{f}{f_c}\right)^2-1}}\right]$
$TE_{1,1}$	$\frac{0.01107}{a^{3/2}}\left\{\frac{\frac{a}{b}\left(1+\frac{a}{b}\right)\left(\frac{f}{f_c}\right)^{3/2}+\left[1+\left(\frac{a}{b}\right)^2\right]\left(\frac{f}{f_c}\right)^{-1/2}}{\left[1+\left(\frac{a}{b}\right)^2\right]^{3/4}\sqrt{\left(\frac{f}{f_c}\right)^2-1}}\right\}$
$TM_{1,1}$	$\frac{0.01107}{a^{3/2}}\left\{\frac{\left[1+\left(\frac{b}{a}\right)^3\right]\left(\frac{f}{f_c}\right)^{3/2}}{\left[1+\left(\frac{b}{a}\right)^2\right]^{3/4}\sqrt{\left(\frac{f}{f_c}\right)^2-1}}\right\}$

The variation of attenuation with frequency in a typical rectangular wave guide is given in Fig. 10 for some of the lower modes of propagation. In Fig. 11, the variation of attenuation with frequency is given for the dominant $TE_{1,0}$ mode for a number of widely used guide sizes over the frequency range for which the guide is recommended.
Fig. 10. Attenuation in typical rectangular, air-filled copper wave guide.

11. Circular Wave Guides. Attenuation formulas for various modes in circular, copper wave guide are given in Table 4. The guide radius a should be given in inches. The variation of attenuation with frequency for each of the above modes in a copper wave guide of 2 in. inside diameter is given in Fig. 12. Note that the attenuation of the $TE_{0,1}$ mode decreases without limit with increasing frequency.[1] Experimental verification of this is lacking, and this anomalous attenuation charac-

[1] Kemp, J., Anomalous Attenuation in Waveguides, *Wireless Engr.*, **23** (275), 211, August, 1946.

Table 4. Attenuation in Circular, Copper Wave Guides

f = frequency
f_c = cutoff frequency
Radius a in inches
Mode	α, Db/Ft
$TE_{1,1}$ (dominant)	$\frac{0.00423}{a^{3/2}}\left[\frac{\left(\frac{f}{f_c}\right)^{-1/2}+\frac{1}{2.38}\left(\frac{f}{f_c}\right)^{3/2}}{\sqrt{\left(\frac{f}{f_c}\right)^2-1}}\right]$
$TM_{0,1}$ (circular magnetic)	$\frac{0.00485}{a^{3/2}}\left[\frac{\left(\frac{f}{f_c}\right)^{3/2}}{\sqrt{\left(\frac{f}{f_c}\right)^2-1}}\right]$
$TE_{0,1}$ (circular electric)	$\frac{0.00611}{a^{3/2}}\left[\frac{\left(\frac{f}{f_c}\right)^{-1/2}}{\sqrt{\left(\frac{f}{f_c}\right)^2-1}}\right]$

teristic is lost if the guide is elliptical. Nevertheless, this mode offers the lowest attenuation of any of the lower wave-guide modes, provided troublesome effects from other modes which are above cutoff can be eliminated. The changes in attenuation caused by small amounts of ellipticity are small in magnitude unless the frequency is far above cutoff.

12. Comparison of Theoretical and Measured Attenuations. The values of attenuation given in the preceding paragraphs are all derived from theoretical considerations. Because the current in a wave guide is concentrated at the inner surface of the guide, the condition of this surface affects the attenuation, which is usually higher than predicted theoretically. The difference will generally be small at the low end of the microwave spectrum, but at higher frequencies surface roughness will increase the attenuation by increasing the path length which the surface current must travel. For example, at 25,000 Mc, even a well-machined surface will frequently have only two-thirds the theoretical conductivity of an ideal surface. Drawn brass tubing usually approaches rather closely the theoretical values at most microwave frequencies.

FIG. 11. Theoretical attenuation of copper wave guide over the recommended operating frequency range for the dominant mode. Dimensions are outside measurements and wall thickness.

The skin depth in most wave guides is so small that if the surface of the guide is plated to a thickness of a thousandth of an inch or less, essentially all of the surface

current will flow in the plated surface metal. But because of the porosity of the plated surfaces, the attenuation will be somewhat higher than expected from the l-f resistivity of the plated metal. The condition of the surface before plating and the plating technique will have considerable effect upon the attenuation. For these reasons, attenuation in plated wave guides varies considerably from sample to sample, and at 10,000 Mc will frequently be half again as great as the theoretical value.
Fig. 12. Attenuation in typical circular, air-filled copper wave guide.

If the inside of a wave guide is coated with a thin protective coating of high-resistance material, such as protective lacquer, the current will flow under this layer in the base metal, and the attenuation will not be greatly affected.

13. Attenuation in Wave Guides below Cutoff. At frequencies below cutoff, wave guides are unable to support traveling waves which carry energy down the guide, and if modes are excited by some launching mechanism, the field intensity will diminish very rapidly with increasing distance from the point of excitation.[1] The input impedance of a wave guide below cutoff is a pure reactance.

For any one mode in the wave guide, the field strength as a function of the distance from the point of excitation will vary as

$$E = E_0\epsilon^{-\alpha z} \tag{13}$$

where E_0 is the initial amplitude at the point of excitation. The attenuation is given by

$$\alpha = 8.69\sqrt{\left(\frac{2\pi}{\lambda_c}\right)^2 - \epsilon\left(\frac{2\pi}{\lambda}\right)^2} \quad \text{db/unit length} \tag{14}$$

where λ_c = cutoff wavelength of air-filled guide
λ = wavelength in free space at frequency of excitation
ϵ = dielectric constant of dielectric medium inside wave guide

At frequencies much lower than the cutoff frequency, the attenuation is very nearly independent of frequency, approaching a limiting value at low frequencies of

$$\alpha = \frac{54.6}{\lambda_c} \quad \text{db/unit length} \tag{15}$$

[1] Linder, E. G., Attenuation of Electromagnetic Fields in Pipes Smaller than the Critical Size, *Proc. IRE*, **30** (9), 412, September, 1942.

For the two modes of greatest interest in circular wave guide, the modes that are commonly used in wave-guide below-cutoff attenuators, the attenuations are as follows:

For the $TE_{1,1}$ mode,

$$\alpha = 8.69 \sqrt{\left(\frac{1.841}{a}\right)^2 - \left(\frac{2\pi}{\lambda}\right)^2} \quad \text{db/unit length} \tag{16}$$

For the $TM_{0,1}$ mode,

$$\alpha = 8.69 \sqrt{\left(\frac{2.405}{a}\right)^2 - \left(\frac{2\pi}{\lambda}\right)^2} \quad \text{db/unit length} \tag{17}$$

where a is the guide radius and λ the free-space wavelength.

14. Wave Guides Filled with Dielectric Material. If a wave guide is partially or completely filled with some dielectric material, the characteristics of the guide will be modified. In dealing with these modifications, it is convenient to regard the dielectric constant ϵ of the material as complex and of the form

$$\epsilon = \epsilon' - j\epsilon'' \tag{18}$$

The loss tangent of the dielectric is then defined by

$$\tan \delta = \frac{\epsilon''}{\epsilon'} \tag{19}$$

For all but high-loss dielectrics, the loss tangent is very nearly equal to the power factor, and the two terms are frequently used interchangeably.

For all modes in wave guides, the cutoff wavelength of a dielectric-filled guide λ_c' is related to the cutoff wavelength of the same guide when air-filled λ_c by

$$\frac{\lambda_c'}{\lambda_c} = \sqrt{\epsilon} \tag{20}$$

The wave-guide wavelength in dielectric-filled guide for all modes is given by

$$\lambda_g = \frac{\lambda}{\sqrt{\epsilon' - (\lambda/\lambda_c)^2}} \tag{21}$$

where λ_c is the cutoff wavelength in the same guide when air-filled.

The standing-wave ratio associated with the reflection from an air-dielectric interface normal to the axis of the wave guide is, for TE modes,

$$\text{SWR} = \sqrt{\frac{1 - (\lambda/\lambda_c)^2}{\epsilon' - (\lambda/\lambda_c)^2}} \tag{22}$$

and, for TM modes,

$$\text{SWR} = \frac{1}{\epsilon'} \sqrt{\frac{\epsilon' - (\lambda/\lambda_c)^2}{1 - (\lambda/\lambda_c)^2}} \tag{23}$$

This reflection can be minimized by tapering the interface in the axial direction.

The attenuation in a below-cutoff wave guide filled with dielectric is given in Eq. (14).

In a wave guide above cutoff filled with dielectric, the attenuation resulting from dielectric losses is given by

$$\alpha = 27.2 \frac{\epsilon''}{\lambda} \frac{1}{\sqrt{\epsilon' - (\lambda/\lambda_c)^2}} \quad \text{db/unit length} \tag{24}$$

The conductor losses are also affected by the dielectric. To find the conductor losses in a dielectric-filled wave guide, it is necessary to modify the expressions in Tables 3 and 4 as follows: (1) In all expressions, replace f_c, the cutoff frequency of the air-filled guide, by $f_c/\sqrt{\epsilon}$, the cutoff frequency of the dielectric-filled guide; (2) multiply the resulting expression by $\epsilon^{1/4}$.

The total attenuation in a dielectric-filled wave guide is the sum of the attenuation resulting from dielectric losses and that resulting from conductor losses.
Fig. 13. Field intensities in a rectangular wave guide partially filled with a dielectric operating in the $TE_{1,0}$ mode.

15. Wave Guides Partially Filled with Dielectric.[1] If a wave guide is partially filled with a dielectric, its properties will, as expected, be intermediate between air-filled and dielectric-filled guides. The fields inside the guide tend to be pulled inside the medium with the higher dielectric constant. The distribution of the fields for a wave guide partially filled with dielectric is shown in Fig. 13, and it is apparent how the point of maximum electric field strength, normally in the center of the guide, has been pulled toward the dielectric.

Placing the dielectric inside the guide will increase the cutoff wavelength and reduce the wave-guide wavelength, but the magnitude of the effect will depend upon the location of the dielectric. The effects will be small, for example, if the dielectric is placed in a region of a weak electric field, as shown in Fig. 14, but will be much greater if the dielectric is placed in the center of the guide, in a region of strong field.

When the dielectric is tapered to minimize the reflection from a transition between dielectric-filled and air-filled guides, it is advisable to start and end the taper in the regions of the weak field. For example, with the $TE_{1,0}$ mode in rectangular wave guides, the best results are found with a taper constructed as shown in Fig. 15.

Dielectric in a region of weak electric field, small effect

Dielectric in a region of strong electric field, considerable effect
Fig. 14. A dielectric placed in a region of strong electric field will have a greater effect upon the properties of the wave guide than if it is placed in a region of weak field.

Fig. 15. Impedance discontinuity at the junction of air-filled wave guide and dielectric-filled wave guide can be minimized by tapering the dielectric.

16. Dielectric Wave Guides. It is possible for a dielectric cylinder immersed in a medium of lower dielectric constant to act as a wave guide in the absence of any conducting surface.[2] Such a wave guide without metal walls has many properties

[1] Pincherle, L., Electromagnetic Waves in Metal Tubes Filled Longitudinally with Two Dielectrics, *Phys. Rev.*, **66** (5, 6), Sept. 1 and 15, 1944.

[2] For example, see Ramo and Whinnery, *loc. cit.*

similar to more conventional wave guides; energy is carried in *TE* or *TM* modes, and the guide acts as a high-pass filter, with the cutoff frequency different for the different modes. But the electromagnetic fields are not confined to the inside of the dielectric cylinder, and a considerable fraction of the total energy carried by the guide is found in the fields that are external to the cylinder. This introduces a number of practical difficulties into the use of these dielectric wave guides. Any mechanical support for the guide interferes with the fields which are external to the dielectric cylinder, and constitutes a discontinuity in the transmission line. Furthermore, this discontinuity results not only in a partial reflection of the transmitted wave, but also in a partial loss of energy by radiation. A similar loss of energy by radiation will occur at a bend in the dielectric transmission line.

17. Obstacles and Discontinuities in Wave Guides. A metallic obstacle placed in a wave guide will in general affect the transmission of an electromagnetic wave through the guide. The obstacle will cause a partial reflection of the incident wave and, in addition, will excite other of the wave-guide transmission modes. If these are also above cutoff, part of the energy in the incident wave will be carried away from the discontinuity by these other modes of transmission. If the modes excited by the discontinuity are below cutoff, they will diminish rapidly in strength with increasing distance from the discontinuity and will draw no real power. They do contribute a reactive effect at the discontinuity, however.

Fig. 16. Equivalent susceptance of a thin symmetrical inductive window in a rectangular guide. Theoretical curves, experimental points.

The effect of an obstacle in a wave guide is equivalent to that of a discontinuity in a conventional transmission line, and it is convenient for engineering work to set up an
FIG. 17. Equivalent susceptance of thin asymmetrical inductive window in rectangular wave guide.

equivalent transmission line and lumped constant circuit for the wave-guide structure. This equivalent circuit will in general be a function of frequency.

If the obstacle has axial dimensions that are very small, *e.g.*, a thin metallic window that partially blocks the guide, the equivalent circuit will be a simple susceptance shunting the guide that is located precisely at the point of discontinuity.[1] If the obstacle is of appreciable thickness, a more complex equivalent circuit in the form of a tee or pi network is usually required, the precise circuit depending upon what planes in the wave guide are chosen for reference.

If two obstacles are placed close enough together for interaction of the below-cutoff higher-order modes, the equivalent circuits will be correspondingly modified. Interaction effects are usually small if the spacing is greater than a quarter-wave-guide wavelength.

The equivalent circuits given in this chapter are in general applicable when the wave guide is above cutoff for the dominant mode only.

18. Obstacles in Rectangular Wave Guide. *Thin Metallic Windows.*[2] A thin metallic window that partially blocks the guide has an equivalent circuit consisting of a susceptance shunting the guide at the location of the window. If the window is of the type shown in Fig. 16, the

[1] Whinnery, J. R., and H. W. Jamieson, Equivalent Circuits for Discontinuities in Transmission Lines, *Proc. IRE*, **32** (2), 98, February, 1944. Also Schelkunoff, S. A., "Electromagnetic Waves," p. 490, Van Nostrand, 1943.

[2] Miles, J. W., The Equivalent Circuit for a Plane Discontinuity in a Cylindrical Wave Guide, *Proc. IRE*, **34** (10), 728, October, 1946.

equivalent circuit is an inductive susceptance, whose magnitude is given in Fig. 16 as a function of the window dimensions. The curves are for infinitely thin windows, the experimental points for windows of 1/32 in. thickness at a wavelength of 6.0 cm. The effect of finite thickness is to increase the susceptance of the window, and series reactance terms in the equivalent circuit are also necessary if the thickness is considerable.

If the opening in the diaphragm is of the type shown in Fig. 17, the equivalent circuit is again a shunt inductive susceptance. The susceptance as a function of the dimensions is given in Fig. 17, along with some experimental results, taken with a window 1/32 in. thick at a wavelength of 6.0 cm.

If the window is of the type shown in Fig. 18, the equivalent circuit is a capacitive susceptance shunted across the guide. The theoretical susceptance for an infinitely thin window is given in Fig. 18. With a window of this type, it is very important for accurate results to take into account the finite thickness of the window. If the window thickness is finite but much less than a wavelength, its susceptance will be given by

FIG. 18. Equivalent susceptance of a thin capacitive window in rectangular wave guide. Theoretical curves for infinitely thin window.

$$\frac{B}{Y_0} = \frac{B_0}{Y_0} + \frac{2\pi t}{\lambda_g}\left(\frac{b}{d} - \frac{d}{b}\right) \tag{25}$$

where B_0/Y_0 = thin window susceptance taken from Fig. 18
λ_g = wave-guide wavelength
t = window thickness

A window of the type shown in Fig. 19 exhibits susceptance vs. frequency characteristics similar to those of a parallel resonant circuit shunting the wave guide. The resonant wavelength, at which the window introduces no reflection, may be determined approximately from the expression

$$\frac{a}{b}\sqrt{1-\left(\frac{\lambda}{2a}\right)^2} = \frac{a'}{b'}\sqrt{1-\left(\frac{\lambda}{2a'}\right)^2} \tag{26}$$

where a and b = inside guide dimensions
a' and b' = window dimensions, as shown in Fig. 19
λ = free-space wavelength

The slope at resonance of the susceptance vs. frequency curve decreases as the height of the window opening increases.
Fig. 19. Resonant window in a thin metallic diaphragm.

Metallic Posts. A round metallic post symmetrically located in a rectangular wave guide, as shown in Fig. 20, has an equivalent circuit consisting of an inductive susceptance shunted across the guide at the location of the post. The magnitude of this susceptance is given as a function of the post diameter.

If the post extends only part way across the guide, as in Fig. 21, the equivalent circuit is a capacitive susceptance, whose magnitude depends upon the length and diameter of the post. At any one frequency, as the length of the post is increased, a position is found at which the susceptance becomes infinite in magnitude. As the frequency is varied about this value, the variation of susceptance vs. frequency is
Fig. 20. Equivalent susceptance of round metallic post in a rectangular wave guide.

similar to that of a series-resonant circuit shunting the wave guide. The resonant wavelength is found when the post length is approximately one-quarter of a free-space wavelength, slightly less for posts of larger diameter.

Resonant Rings. A rectangular metal ring placed in a rectangular wave guide perpendicular to the axis also exhibits characteristics similar to a series-resonant circuit shunting the guide. The resonant wavelength depends upon the mean perimeter of the ring and is found when the perimeter is somewhat greater than a full wavelength.

Fig. 21. Resonant metallic post in rectangular wave guide.

19. Obstacles in Circular Wave Guides. For a wave guide which is above cutoff for the $TE_{1,1}$ mode only, a thin diaphragm with a centered, circular hole behaves as a shunting inductive susceptance. The magnitude of this susceptance as a function of the hole diameter is given in Fig. 22. A thin metal disk centrally located in the wave guide behaves as a capacitive susceptance shunted across the guide.

A variety of apertures in thin diaphragms act as parallel resonant circuits shunting the guide, and for each of these apertures it is usually possible to find a similar obstacle which acts as a series-resonant circuit shunting the guide. Some examples of these circuits are shown in Fig. 23.

FIG. 22. Measured equivalent susceptance of a circular hole in a thin diaphragm in a circular wave guide operating in the $TE_{1,1}$ mode. The operating wavelength was 3.2 cm; window thickness, 1/32 in.

20. Miscellaneous Wave-guide Structures.[1] *Bends.* The direction of transmission in a wave guide may be changed by bending the guide. The bent section has characteristics slightly different from the straight guide, and consequently there will be an impedance discontinuity at the junction of the bent and straight sections. A number of modes will be excited at the discontinuity and may carry away appreciable power if the guide is above cutoff for those other modes.

FIG. 23. Wave-guide structures equivalent to resonant circuits shunting the wave guide. Circular wave guide operating in the $TE_{1,1}$ mode with electric field vertically polarized.

If the guide is operating with the dominant mode and if all other modes are below cutoff, a bend is usually a very satisfactory way of changing direction of transmission. For rectangular guides, there are two types of bend, shown in Fig. 24, known as E-plane and H-plane bends, in the plane of the electric and magnetic fields, respectively. If the inner radius of the bend is a wave-guide wavelength or greater, the reflection from the bend will be small (SWR < 1.05) over the normal operating range of the wave guide. The radius may be much smaller and still yield satisfactory results if the bend is carefully fabricated. With a sharp bend, the cross section of the guide should be undistorted for best operating results.

A bend in a circular wave guide operating in the $TE_{1,1}$ mode, if not in the plane of polarization or normal to that plane, will split the transmitted wave into two components with different phase velocities and cause elliptical polarization of the trans-

[1] Moreno, T., Wave Guide Transmission Systems, *Electronics*, **19** (6), 136, June, 1946.

mitted wave. If the plane of the bend is in one of the planes of mode symmetry, the radius of the bend can be considerably less than a wave-guide wavelength, and the bend will give satisfactory results if the cross section is not distorted.
FIG. 24. Bends in rectangular wave guide.

Corners. An abrupt corner is in general not a satisfactory means of changing the direction of transmission in a wave guide, as an appreciable reflection will be set up for all but very small changes in direction. If the desired angular change is accomplished with the use of two simple corners, spaced apart approximately a quarter-wave-guide wavelength, the reflections from the two corners will tend to cancel each other. For E-plane corners, shown in Fig. 25, the optimum spacing is very close to a quarter-wave-guide wavelength at all wavelengths, but for H-plane corners, the optimum spacing is slightly different and is plotted as a function of λ/a in Fig. 25 for 90 deg total change in direction.

The band width over which these corners will introduce a standing-wave ratio less than 1.05 is between 6 and 20 per cent for a 90-deg bend, being larger for smaller values of λ/a. Circular bends are preferred for larger angles and greater band widths.

The reflection from a corner may also be eliminated by modifying the corner as shown in Fig. 26, and the band width will be comparable to that obtained with the
FIG. 25. Corners, 90 deg, designed for minimum reflection. Optimum dimensions for *H*-plane corners in graph; for *E* corners, in box. λ_g is wave-guide wavelength.
FIG. 26. Minimum reflection corners with dimensions as function of angle.

double corner. The required dimensions for E- and H-plane bends are given in Fig. 26 as a function of the angle. Manufacturing tolerances must be held rather closely on these corners for optimum performance.

Twists. The direction of polarization in a rectangular wave-guide transmission system may be changed by twisting the guide about its axis (Fig. 27). If carefully fabricated, these twists will introduce no appreciable reflection into a matched transmission system. A 90-deg twist will generally introduce a standing-wave ratio below 1.1 if more than $2\lambda_g$ in length, and shorter twists are equally satisfactory if carefully made.

FIG. 27. Twist in rectangular guide to change direction of polarization.

21. Wave-guide Connectors. Two sections of a wave guide may be connected by machining the two ends of the guide off square and clamping them together. This is a very satisfactory connection if the guides are carefully aligned and tightly clamped, and the butt joint will be electrically smooth and free from loss. The efficiency of the connection depends critically upon the accuracy of the joint, however. If the two guides are slightly misaligned or not tightly clamped, or if the ends are not finished off square and smooth, the loss and reflection may be relatively large. Losses of up to 1.0 db have been measured on butt connections that appeared satisfactory to a superficial examination. So while butt joints may be very satisfactory and are even preferred when accurate measurements are being made, they must be assembled with care and accuracy to give satisfactory performance.

The assembly of wave-guide components is facilitated with the use of choke couplings, as shown in Fig. 28. These offer advantages in flexibility and reliability over

simple butt joints because their performance does not depend critically upon the tightness of the connection. The L-shaped cavity between the choke and flange is effectively a half-wave, shorted transmission line, which is in series with the guide and offers a minimum discontinuity. The circular slot in the choke is $\lambda/4$ deep, and the actual contact between choke and flange is in series with the high-input impedance of this resonant slot, and is at a point of minimum current. For this reason, a poor contact between choke and flange does not impair the efficiency of the connection. The distance between the quarter-wave slot and the inside of the wave guide must be determined experimentally, but is effectively $\lambda/4$. For maximum band width, the slot width should be several times greater than the spacing between choke and flange faces. A properly designed choke will introduce a standing-wave ratio less than 1.05 over most of the usable range of a rectangular wave guide.

It is not necessary that the outer faces of the choke and flange be in contact for good performance. The connectors may be used as nonrigid couplings, such as are required when a shock-mounted chassis is connected to a rigidly mounted line. If a clearance of $\frac{1}{16}\lambda$ is allowed between choke and flange, a sidewise displacement of up to $\frac{1}{16}\lambda$ will not raise the loss above 0.3 db, or the standing-wave ratio above 1.3, for frequencies within a few per cent of the design frequency. A pair of chokes may be used instead of the choke-flange combination for a wobble joint and may have superior performance. With paired chokes there are often resonances encountered near the design wavelength which manifest themselves by sharp increases in the loss and standing-wave ratio.

FIG. 28. Choke-flange connector for rectangular wave guide.

22. Launching of Waves in Wave Guides. Energy traveling down a conventional transmission line may be transferred to a wave guide by terminating the transmission line in an antenna structure, which, instead of radiating energy into free space, is mounted inside the wave guide. The transition from conventional transmission line to wave guide may be made electrically smooth and reflectionless by designing the antenna so that it presents a matched load to the transmission line. By the law of reciprocity, a wave traveling from the wave guide to the transmission line will likewise not be reflected, provided the loss in the transition section is small.

The case of greatest practical interest is the launching of a $TE_{1,0}$ mode in rectangular wave guide from a coaxial transmission line. The axis of the coaxial line is generally made normal to the broad face of the rectangular wave guide. As illustrated in Fig. 29*a*, the outer conductor of the coaxial line is terminated at the wall of the wave guide, but the inner conductor extends into the wave guide, parallel to the electric lines of force, and forms a probe antenna which radiates down the guide.[1]

If the wave guide is terminated in both directions in its characteristic impedance, the power input from the coaxial line will divide equally in the two directions. To send the energy in a single direction down the wave guide, one end is shorted with a metal plate. The distance of this plate from the antenna structure and the length of the antenna are chosen to present a matched impedance to the coaxial line. Experimental determination of the optimum dimensions is usually required.

The band width over which the impedance transition between coaxial line and wave guide is relatively smooth and reflectionless can be increased by increasing the diameter of the probe antenna. Further improvements may be realized by modifying the structure as shown in Fig. 29*b*. The structures shown in Fig. 29*c* and *d* are

[1] Moreno, *loc. cit.*
FIG. 29. Broad-band, fixed-tuned coaxial line to wave-guide transformers providing reflectionless transmission.

also broad-band transitions between coaxial line and wave guide, and provide the additional advantage of a mechanical support for the center conductor of the coaxial line. Again, the optimum dimensions for these structures must be determined experimentally.

23. Mode Transformers for Wave Guides. It is sometimes desirable in wave-guide transmission systems to change from one mode of transmission in one wave guide to a second mode of transmission in another guide. These transformers may be designed in a variety of ways, of which the following examples are illustrative:

FIG. 30. Tapered transmission between rectangular and circular wave guides, both operating in dominant mode.

An example of the simplest type of transformer is that required to change from the $TE_{1,0}$ mode in rectangular wave guide to the $TE_{1,1}$ mode in circular wave guide. Because of the similarity of these two modes, it is only necessary to construct a continuous taper in the guide cross-sectional dimensions, as shown in Fig. 30. If the taper is sufficiently long ($2\lambda_g$ is usually sufficient) the required mode transformation will be accomplished with a minimum of discontinuity and reflection in the transmission system.

A more complex transformer is required for the transition to higher modes in one

or both guides, *e.g.*, the transition from $TE_{1,0}$ mode in rectangular guide to $TM_{0,1}$ mode in a circular wave guide. Several transformers have been designed to accomplish this result, some of which are illustrated in Fig. 31. The problem is more difficult because the transition section may excite a large number of modes in the circular wave guide, and the dominant $TE_{1,1}$ mode as well as the desired $TM_{0,1}$ mode will be above cutoff. The transformer must therefore be carefully designed so as to minimize the excitation of the undesired $TE_{1,1}$ mode, whether by reasons of symmetry or by other techniques. Mode suppressors are also useful in the design of these transformers. Resonant rings are used for this purpose; when properly designed, they will completely reflect the $TE_{1,1}$ mode and have negligible effect upon the $TM_{0,1}$ mode. One of these resonant rings is shown in the transformer of Fig. 31*a*, placed in a position to minimize the excitation of the $TE_{1,1}$ mode in the circular wave guide.

FIG. 31. Transformers from $TE_{1,0}$ mode in rectangular to $TM_{0,1}$ mode in circular wave guide. In addition to providing smooth transition between desired modes, these transformers should not excite the dominant $TE_{1,1}$ mode in the circular wave guide which is above cutoff.

In Fig. 31*b*, the stub section of round wave guide extending below the junction with the rectangular guide is effectively in series with the rectangular and round guides. The length and diameter may be chosen so that the stub is effectively $\lambda/2$ long for the desired $TM_{0,1}$ mode, but effectively $3\lambda/4$ for the $TE_{1,1}$ mode. The stub therefore offers an infinite impedance in series with the guide for the $TE_{1,1}$ mode, but a zero impedance for the $TM_{0,1}$ mode. In all these transformers, a matching diaphragm may be used to eliminate any residual reflection from the transition.

24. Multimode Wave Guides. Multimode guides offer two significant advantages to the designer of microwave transmission systems. Through them, transmission over a broader band of frequencies is possible. They produce lower losses and less delay distortion than wave guides using the dominant mode. Thus, many more channels of a given width can be transmitted over a multimode guide than over a guide transmitting in the dominant mode only.

FIG. 32. Faraday rotation caused by ferrite in wave guide.

In multimode applications, each of the modes has to be launched and withdrawn without disturbing the other modes present. Recent work done on these problems will be found in the literature.[1]

[1] Beck, A. C., Measurement Techniques for Multimode Waveguide, *Trans. IRE*, **MTT-3** (3), 35, April, 1955. King, A. P., Dominant Waveguide Transmission Characteristics of a Multimode Round Waveguide, *Proc. IRE*, **40**, 966, August, 1952. Miller, S. E., and A. P. King, Low-loss Waveguide Transmission, *Proc. IRE*, **41**, 348, March, 1953. Miller, S. E., Waveguide as a Communication Medium, *Bell System Tech. J.*, **33**, 1209, November, 1954. Miller, S. E., Coupled Wave Theory and Waveguide Applications, *Bell System Tech. J.*, **33**, 661, May, 1954.

Probes, loops, and iris structures have been used successfully. Transducers located at the ends of the guide have become useful. Modes may also be separated by their discrete attenuation-coefficient values. Mode filters that use sheets of resistive material running parallel to the E vector of the mode to be attenuated have been applied successfully. It is also possible to discriminate between modes by making use of their different velocity of propagation. Multimode work permits application of real ingenuity since it is still a fast-growing field.

FIG. 33. Rotation and loss of ferrite rotator.

25. Ferrites in Wave Guides. At microwave frequencies[1] and in a static magnetic field, propagation characteristics of phase, polarization, and transmission loss vary with the magnetic field intensity in a wave guide containing ferrite materials.
FIG. 34. Rotation as function of frequency.

Ferrite inserted into a wave guide and magnetized in the direction of propagation porduces a rotation of the plane of polarization in accordance with the Faraday effect. Figure 32 shows the rotation caused by a cylindrical piece of magnesium-manganese ferrite ¼ in. in diameter and 1½ in. long inserted into the center of a standard 1- by ½-in. wave guide at 9,375 Mc. An axial magnetic field is provided by a solenoid wound around the wave guide. At magnetic saturation, the ratio of transmission loss in the ferrite to the rotation of the plane of polarization produced by it is constant.

Figure 33 shows, at saturation, the plane-of-polarization rotation per unit length as a function of ferrite-rod diameter, and Fig. 34 shows, under saturation conditions, how normalized rotation varies with frequency for several ferrite-rod diameters.[2]

Rectangular guides may also be loaded with ferrites; Fig. 35 shows the geometry for this case.

FIG. 35. Geometry of ferrite-loaded wave guide.

[2] Sakiotis, N. G., and H. N. Chait, Properties of Ferrites in Waveguides, *Trans. IRE*, **MTT-1** (2), 11, November, 1953.

If a magnetizing field perpendicular to the broad face of the guide is applied as in Fig. 35, it is possible to obtain either reciprocal or nonreciprocal propagation through the guide. Nonreciprocal propagation is produced by nonsymmetrical insertion while reciprocal propagation is the result of symmetrical insertion; Fig. 36 shows phase shift and rotation to be identical in both directions for this case.

One-way transmission lines can be con-
FIG. 36. Result of symmetrical placement of ferrite in wave guide.
FIG. 37. Ferrite placed against one wall produces one-way transmission.

structed by placing the ferrite in the wave guide against one side wall, as in Fig. 37. This produces the desired nonreciprocal characteristics. Nonreciprocal and reciprocal behavior of ferrite-loaded wave guides is due to gyromagnetic resonance in the ferrite material. If the r-f magnetic field is circularly polarized in a plane perpendicular to the magnetization of the ferrite, the r-f power absorption in the ferrite will show a pronounced peak
FIG. 38. Polarization of the H vector, $TE_{1,0}$ mode.
FIG. 39. One-way transmission produced by ferrite.

at a value of the magnetizing field which produces gyromagnetic resonance, provided that the sense of the circular polarization is positive relative to the magnetizing field. For a negative sense of circular polarization this absorption peak fails to materialize. These relations are shown in Fig. 38.

In wave-guide propagating in the $TE_{1,0}$ mode there are two parallel planes so

located that the H vector is polarized circularly in one sense in the one, and in the other sense in the other. The figure shows variation of the amplitudes of the two quadrature components of the H vector across the guide cross section. The two components are of equal magnitude at the two equally spaced planes mentioned above and here the magnetic r-f field is circularly polarized. The longitudinal field component, however, is of opposite sign at these planes, which indicates a 180-deg phase difference.

If some ferrite material is located at one of these planes and the static magnetic field is adjusted for gyromagnetic resonance at the r-f frequency, one direction of propagation will experience much absorption while there will be little absorption in the other. Some values measured by Sakiotis and Chait[1] are shown in Fig. 39. Application of ferrites to wave guides is still in the development stage. It has permitted many valuable systems applications.[2]

26. Coupling through Holes between Wave Guides.[3] For a rectangular wave guide operating in the $TE_{1,0}$ mode, the circuit equivalent of a small centered hole in an infinitely thin diaphragm normal to the guide axis in an inductive diaphragm normal to the guide axis is an inductive susceptance shunting the guide (Fig. 40). For waveguide as shown in Fig. 40, and having a hole of diameter d, the susceptance of the hole normalized to the guide admittance is

$$\frac{B}{Y_0} = \frac{3}{2\pi}\frac{ab\lambda_g}{d^3} \tag{27}$$
FIG. 40. Small round hole in thin diaphragm in rectangular guide is equivalent to an inductive susceptance shunting the guide.

The insertion loss of a hole in an infinitely thin diaphragm placed between a matched source and receiver is given by

$$\alpha_1 = 10 \log_{10}\left[\frac{(B/Y_0)^2}{4} - 1\right] \quad \text{db} \tag{28}$$

Finite thickness t of the diaphragm results in an additional attenuation, given by

$$\alpha_2 \cong 32.0\frac{t}{d} \quad \text{db} \tag{29}$$

The over-all attenuation is then given by $\alpha_t = \alpha_1 + \alpha_2$.

When the hole is used to couple energy between two wave guides whose axes are not coincident, the insertion loss of the coupling hole may in many cases be calculated by a simple modification of the term α_1 of Eq. (28). Examples of arrangements where such simple modifications are possible are shown in Fig. 41. The factor α_2 is not affected by the position of the hole. If the hole is in the broad face of the guides, the problem of coupling is more complex, but a complete solution has been given by Bethe.[4]

FIG. 41. Attenuation through small hole separating two sections of rectangular guide, under various conditions of operation.

27. Wave-guide Tees and Junctions.[1] The joints in wave guides are of two types, as shown in Fig. 42.

1. *H-plane Tee or Shunt Tee.* The branch guide is taken off the narrow side of the main guide in the plane of the magnetic field. This is called a *shunt tee* because a signal fed in the branch guide will divide at the junction and be in phase in arms 1 and 3 at points equidistant from the junction. The equivalent circuit for two-wire transmission lines is shown in Fig. 42.

2. *E-plane or Series Tee.* The branch guide is taken off the wide side of the main guide in the plane of the electric field. This is called a *series tee* because a signal fed in the branch guide will divide at the junction and be out of phase in arms 1 and 3 at points equidistant from the junction. The equivalent circuit for two-wire transmission lines is shown in Fig. 42.
FIG. 42. Two kinds of tee joints in rectangular wave guide and their two-wire transmission-line equivalent circuits. The E-plane tee is partially cut away to show an added matching diaphragm.

As would be expected from the equivalent circuits for these tee joints, positions may be found in the branch arms at which short circuits may be placed to give reflectionless transmission past the branch, and other positions may be found at which a short circuit may be placed to give a complete reflection of energy at the branch arm. But because of the distortion and fringing fields at the junction, the positions at which these short circuits must be placed to realize these effects will be somewhat different from the values predicted by conventional transmission-line theory, which neglects these field distortions. For example, with the shunting arm, one would expect that a short circuit should be placed $\lambda/4$ or $3\lambda/4$ away from the junction to give reflectionless transmission past the branch arm. Experimentally, this value is found to vary

[1] Allanson, J. T., R. Cooper, and T. G. Cowling, The Theory and Experimental Behavior of Right-angled Junctions in Rectangular-section Wave Guides, *J. IEE*, **93** (23), Pt. III, 177.

with ratio of operating wavelength to cutoff wavelength, a typical mid-band value being 0.57λ from short to inside face of the main guide.

Judging by the equivalent circuit, it should be possible to obtain reflectionless transmission around a corner by proper location of a short in the straight-through arm of the wave guide. Experimentally it is found that the reflection may be minimized but not eliminated by proper positioning of the short. This minimum reflection varies with operating wavelength; in typical operation the minimum standing-wave ratio may be approximately 1.3.

To obtain reflectionless transmission around a corner with a tee junction, it is necessary to add some sort of matching structure, such as a diaphragm, the reflection from which is adjusted to cancel the residual reflection from the tee. A typical matching structure of this sort as placed in the branch arm is shown in Fig. 42.

Fig. 43. Magic tee in rectangular guide.

28. Wave-guide Bridge Structures. A variety of wave-guide structures may be built which have properties similar in many respects to l-f bridge circuits. These structures utilize tee joints of the two types discussed in the previous paragraphs.

The best known of these bridge circuits is the *magic tee*, or *hybrid tee*, shown in Fig. 43. Two branch wave guides are connected to a colinear wave guide at the same point, one in an H plane, shunt tee and the other in an E plane, series tee. If a signal is fed in the shunt arm 4, and the two colinear arms 1 and 2 are terminated in their characteristic impedances, the input power will, for reasons of symmetry, divide equally between the two load impedances. Also for reasons of symmetry, there will be no signal delivered into arm 3, as there is no net electric vector developed across the entrance to this series arm. The input impedance to the shunt arm will not in general match the characteristic impedance of the wave guide; *i.e.*, there will be standing waves in the input arm.

Fig. 44. Symmetrical four-terminal equivalent of magic tee.

A similar situation will exist if power is fed into the series arm. If the colinear arms 2 and 1 are terminated in their characteristic impedances, the input power will divide equally between these two arms, and no power will be delivered to the shunt branch arm 4. There will be standing waves set up in the input arm, however.

The symmetry of the structure will not be destroyed if the two matched loads on the colinear arms are replaced by any two impedances that are equal in magnitude and phase angle, and under these conditions there will still be no coupling between the series and the shunt branch arms. It is apparent that the behavior of the structure is similar to a bridge circuit, with the signal fed in one branch arm and the null detector on the other.

With matched loads on the two colinear arms, the impedance measured looking into either of the branch guides does not match the guide impedance. If, by the addition of some sort of matching elements, these impedances are made to match the wave-guide impedance, so that there are no standing waves in the input branch arms, the structure will possess additional qualities of balance.
As before, if power is fed in either branch arm and if the two colinear arms are terminated in matched impedances, the input power will divide equally between these impedances, and there will be no coupling between the two branch arms. Because of the added matching structures, a matched impedance will be seen at the input. In addition, if a signal is fed in one of the colinear arms, it will divide equally between the two branch arms, if they are matched, and there will be no coupling to the other colinear arm. Also, the input impedance to the colinear arms under these conditions will match the guide impedance.
FIG. 45. Cutaway view of magic tee showing impedance-matching diaphragm and post.

FIG. 46. Hybrid coil equivalent of magic tee of Fig. 43.

The matched structure is equivalent to a balanced four-terminal-pair network, shown schematically in Fig. 44, in which each wave guide is represented by a terminal pair. In this equivalent network, if a signal is fed into any terminal pair and if the two adjacent terminal pairs are terminated in matched loads, the power will divide equally between these loads, and no voltage will appear across the opposite terminal pair.

The matching of the branch arms may be accomplished in a variety of ways. For maximum band width, it is desirable to have the matching structure as close as possible to the junction. One typical design is shown in Fig. 45, in which the H-plane tee is matched by the post and the E-plane tee by the asymmetrical inductive diaphragm.

The l-f equivalent circuit of the magic tee is the hybrid coil, shown in Fig. 46, and the properties possessed by the two circuits are equivalent in many ways.

FIG. 47. Rat-race wave-guide bridge, electrically equivalent to magic tee of Fig. 43. The four branching guides connect with the ring in series tees. Distances between branch guides are measured along the mean circumference of the ring.

Several other structures possess properties electrically equivalent to the magic tee. One of these, known as a "ring" or "rat-race" bridge, is shown in Fig. 47. The distance between any two of the branch arms may be increased by an integral multiple number of half wavelengths without affecting the properties of this circuit. For reasons of impedance matching, it is desirable that the height of the wave guide forming the ring be somewhat less than the height of the four incoming guides. The band width of this structure is less than that of the magic tee, but the power-handling capacity is greater.

MISCELLANEOUS WAVE-GUIDE DEVICES

29. Standing-wave Detectors (Impedance Meters). To measure the standing waves in a wave guide, the field strength in the guide must be measured as a function of position along the guide. The fields are completely contained within the outer conducting tube, so this tube must be slotted to allow entry of the probe or loop that samples the field. The slot should have a minimum effect upon the fields in the guide and should therefore be located where there is no current in the wave-guide walls transverse to the slot. For a rectangular wave guide operating in the $TE_{1,0}$ mode, the preferred location is in the center of the broad face of the guide, where the current has only an axial component (Fig. 48).

FIG. 48. Slot for measuring standing waves.

A small fraction of the energy contained in the guide is coupled to a detector by a small probe or loop which extends into the guide through the slot. The coupling probe or loop is mounted on a carriage which moves along the guide, and the signal coupled to the detector depends upon the field strength at the location of the coupling element.

A coupling probe is usually preferred to a coupling loop because of the probe's mechanical simplicity, and because its position may be precisely determined. The probe should not extend into the guide far enough to disturb the field pattern inside the guide, and a penetration of 15 per cent or less of the guide height is considered good operating practice.[1] For this reason, accurate mechanical construction of standing-wave detectors is essential to operating accuracy, for slight variations in probe penetration will cause corresponding variations in the indicated field strength.]

30. Matched Terminations for Wave Guide. Terminations for wave guides which present an impedance that matches the wave-guide impedance may be constructed in a variety of ways. The most successful designs, which remain matched over a considerable band of frequencies, utilize a section of wave guide to which some lossy or resistive element has been added to make it highly attenuating, with a tapered transition between the attenuating section and the incoming wave guide.

FIG. 49. Tapered strip of resistance film mounted inside rectangular guide to provide matched termination.

A relatively lossy dielectric filling the wave guide makes it highly attenuating. The phenolic resin-bonded plastics are satisfactory for this purpose, as are asbestos boards such as Transite which will handle higher powers. The tapered section may be constructed by tapering the dielectric; a taper of the type shown in Fig. 15 has proved satisfactory. If this taper is longer than 2λ, the design is very uncritical to either taper length or dielectric properties, provided a sufficient length of the high-loss dielectric is used in the attenuating section.

For lower power work, resistive films on a dielectric backing are very satisfactory. A platinized film on glass has been used, and carbon films on plastic board are very easy to work with. For maximum attenuation, the resistive film should lie in the plane of the electric field, in a region of strong field. For a rectangular guide in the $TE_{1,0}$ mode, the attenuation is high if the resistive film is placed parallel to the narrow faces of the guide and centered with respect to the broad faces. The attenuation of this lossy section is matched to the input guide by tapering the film to a point as shown in Fig. 49.

[1] Altar, W., F. B. Marshall, L. P. Hunter, Probe Error in Standing Wave Detectors, *Proc. IRE*, **34** (1), 33P, January, 1946.

31. Fixed Attenuators.[1] Fixed attenuators for wave guides can be constructed in a manner similar to matched terminations. The amount of attenuation may be controlled by varying the length of the lossy section, as well as the attenuation per unit length. For fixed attenuators, it is usually necessary to match both ends of the lossy section to the wave guide, so there are tapers at each end of the lossy section. The tapers may be replaced by steps, similar to $\lambda/4$ matching sections. These are physically shorter but are matched over a reduced band width. The attenuation resulting from the use of lossy dielectrics is usually a function of the temperature of the dielectric, and also varies with its exposure to humidity. The resistive films are more satisfactory in this respect. A typical fixed attenuator using a resistive film is shown in Fig. 50.
Fig. 50. Tapered resistance film to form fixed attenuator inside rectangular guide.

Directional couplers, discussed in a subsequent paragraph, are among the most satisfactory fixed attenuators.

32. Variable Attenuators. Variable attenuators used with wave guides fall into two classes: those utilizing the resistive attenuation of lossy dielectrics or resistance films, and those utilizing the reactive attenuation of below-cutoff wave guides. A typical resistive attenuator uses a resistive film of the same type used in matched terminations or fixed attenuators. The attenuation is varied by changing the position of the film within a wave guide, or by varying the amount of resistive film inserted into the wave guide through a slot in its outer wall. An example of the latter type is shown in Fig. 51. These attenuators can be accurate and stable, if carefully designed, and have the distinct advantage that the minimum attenuation may be reduced essentially to zero by removing the film completely from the guide or by moving it to a region of negligible field strength. However, these attenuators require calibration against some standard, at the same or at a different frequency.

The reactive attenuation in a below-cutoff wave guide may be used in a variable attenuator,[2] the variation being accomplished by changing the length of the below-cutoff wave guide. The attenuation in a below-cutoff wave guide may be calculated from the guide dimensions. For the $TE_{1,1}$ and $TM_{0,1}$ modes in round wave guide, the attenuation is given in Eqs. (16) and (17).

Fig. 51. Use of flap of resistance material as a variable attenuator by lowering it into a region of strong electric field.

Typical attenuator designs, in which the below-cutoff wave guides are fed from coaxial lines, are shown in Fig. 52. The input impedance to a below-cutoff wave guide is a reactance, so if the input and output impedances of the attenuator are to match the line impedances, some lossy elements must be added. These may be simply added lengths of lossy lines, or they may be shunt resistance films, as shown schematically in Fig. 52.

For the attenuation in the below-cutoff guides to equal the values given by the above formulas, the launching mechanism should excite only the desired mode in the below-cutoff wave guide. The attenuation in circular wave guide is lowest with the $TE_{1,1}$ mode, so if other modes are excited by the launching mechanism, they will attenuate more rapidly with distance, and the rate of attenuation will approach the

[1] Gaffney, F. J., Microwave Measurements and Test Equipments, *Proc. IRE*, **34** (10), 775, October, 1946.

[2] An example is given in H. R. Meahl, An Attenuator of S-band Energy, *Proc. IRE*, **35** (2), 211, February, 1947.

theoretical value of the $TE_{1,1}$ mode at large attenuations. But attenuators using the $TM_{0,1}$ mode must be very carefully designed so that the undesired $TE_{1,1}$ mode will not be excited; otherwise the $TE_{1,1}$ mode will become increasingly strong relative to the desired $TM_{0,1}$ mode at large spacings and cause a departure from linearity.

Below-cutoff wave-guide attenuators are widely used where a precision variable attenuator is desired, as in signal generators, but their primary disadvantage is the
FIG. 52. Variation in below-cutoff sections as variable attenuators. Resistance films match the below-cutoff section to the input coaxial lines.

large minimum attenuation. If the input and output coupling elements are brought too close together, the calibration will deviate greatly from theoretical values, and in addition the interaction between input and output will vary the impedances presented by the attenuator to the incoming line.

33. Impedance Transformers. Fixed impedance-transforming elements in wave guides frequently consist of the metallic diaphragms described in Sec. 18. These are equivalent to susceptances shunting the wave guide and are employed in the same fashion as stub transmission lines are used to tune conventional transmission-line systems; *i.e.*, if their size and position are correctly determined, these diaphragms are capable of matching any load impedance not a pure reactance to the characteristic impedance of a wave guide.

For tunable impedance-matching devices in wave guides, shorted stub lines of variable length may be used in various combinations, and the series or shunting reactance of the stub guides is varied by changing their lengths. Another type of variable reactance that is well suited to wave-guide structures is the adjustable probe, shown in Fig. 53. The shunt reactance of this probe is varied by changing its penetration into the guide. A typical impedance transformer may utilize two or three of these adjustable probes, fixed in position and spaced along the line. Another very useful design has the probe mounted on a sliding carriage and extending through a slot into the wave guide. With this arrangement, both the penetration and position of the probe may be continuously varied.
FIG. 53. Adjustable probe providing variable reactance shunting the guide. Wave trap gives electrical contact between probe and wave guide without metal-to-metal contact at inner surface of guide.

A special type of impedance transformer is the phase shifter, which is a section of a wave guide whose electrical length is continuously variable. A typical phase shifter, shown in Fig. 54, uses a tapered block of dielectric which partly fills the wave guide. The effect of the dielectric in a wave guide is to reduce the wave-guide wave-

length, but the amount of reduction depends upon the electric field strength where the dielectric is located. So in the design of Fig. 54, as the dielectric block is moved toward the center of the wave guide to a region of greater electric field strength, the wavelength in that section of wave guide will be reduced, and the electrical length of the section of guide will correspondingly increase.
FIG. 54. Continuously variable phase shifter. The electrical length of the wave-guide section is increased by shifting the tapered dielectric block toward center of guide to region of greater electrical field.

34. Directional Couplers.[1] Directional couplers are measurement devices used in conjunction with h-f transmission lines, such as wave guides. They consist of two transmission lines, coupled together at an intersecting point or in an intersecting region. The coupling is in a manner such that an electromagnetic wave traveling in a single direction along one line will induce a wave traveling in a single direction along the second line. A wave traveling in the opposite direction on the second line will be induced by a wave traveling in the opposite direction along the first line.

The performance of a directional coupler may be described in terms of two quantities:

1. *Attenuation.* The attenuation of a coupler is the relative strength of the traveling wave on one line and the traveling wave which it induces on the second.

2. *Directivity.* Only in the ideal coupler does a single traveling wave on one line induce a wave traveling in a single direction on the second line. In a practical coupler, two waves traveling in opposite directions are induced. These are normally greatly unequal in strength, and their relative strength is the directivity of the coupler.

Directional couplers are widely used as fixed attenuators because the attenuation depends upon the coupling between lines. This coupling is generally through holes in the wall separating the two guides and is therefore quite unaffected by changes in temperature and humidity. Directional couplers also have application in the measurement of reflection coefficients and, in addition, permit a signal to be introduced in a single direction on a transmission line without actually breaking into the line.

The schematic diagram of a typical directional coupler is shown in Fig. 55. The two transmission lines are weakly coupled together by two coupling links, spaced $\lambda/4$, as shown. A wave traveling from left to right on the primary line induces through each coupling link two waves traveling in opposite directions on the secondary line. Because of the spacing between coupling links in the primary line, link B will be excited 90 deg in phase behind link A. Because of the spacing between coupling links in the secondary line, the signal traveling to the right from link A will be retarded 90 deg with respect to the corresponding signal from link B, and the two waves will therefore reinforce each other. But the signal traveling to the left from link B will be retarded an additional 90 deg with respect to the corresponding signal from link A; the two

Fig. 58. Coupler construction.

signals will therefore be 180 deg out of phase and will cancel each other. As a result of these actions, the wave traveling from left to right on the primary line induces on the secondary line only a wave traveling from left to right. Correspondingly, a wave traveling from right to left on the secondary line is induced by a wave traveling in that direction on the primary line.
FIG. 59. Adjustable finline double coupler.
FIG. 60. Evolution of flat-strip transmission line.

The coupling elements usually take the form of apertures through the walls of the adjacent wave guides, through which energy is coupled. A number of typical directional couplers are shown in Fig. 56. The two-hole coupler is the wave-guide analogue of the two-element coupler whose operation is described above. The three-hole coupler operates in a similar manner but has high directivity over a greater band of frequencies. The series-stub coupler is similar, but the coupling elements are sections of low-impedance wave guide. The single-hole coupler obtains its directive effect

by having both electric and magnetic coupling through the hole, which reinforce in one direction and cancel in the other. The angle between the guides is chosen so that the two signals are equal in magnitude. The two-slot coupler has high directivity over a broad band because the 180-deg phase shift between the two coupled signals required for cancellation in one direction is accomplished by coupling to elements of magnetic field in one guide that are 180 deg out of phase, this phase difference being independent of frequency.

35. Finline Couplers.[1] The finline coupler permits successful operation over wide

frequency bands. It serves to build up directional couplers, hybrid junctions, and polarization-sensitive devices capable of operating over one or several octaves. The basic device is shown in Fig. 57. A rectangular wave guide is joined to a circular one. Thin metallic fins are inserted diametrically opposed to each other as in Fig. 58. Almost all the energy associated with the field whose electrical vector is parallel to the fins E_P will be guided by the fins and coupled through the hole into the rectangular guide. Energy associated with a transverse field E_T is hardly influenced by the presence of the fins and passes through the coupler. Two waves polarized in two perpendicular planes can be readily separated.

FIG. 64. Distribution of power flow for wide strip of zero thickness above infinite ground plane.

To vary the degree of coupling, two finline couplers may be combined as shown in Fig. 59. The angle between the two rectangular guides determines the distribution of energy between E_3 and E_4. At 45 deg the power is evenly split. Using E_1 as input, the energy is coupled to E_3 and E_4. If the input is at E_4, the energy is divided between E_1 and E_2.

Barnes, Microwave Printed Circuits, National Conference on Airborne Electronics, IRE, Dayton, Ohio, 1951; *Proc. IRE*, MTT-3 (2), March, 1955.

carried out in its direction. In October, 1954, a symposium on microwave strip circuits was held at Tufts College, Medford, Mass., at which a large number of developments were reported.[1]

The flat-strip system has developed rapidly. Printed-circuit techniques have been applied successfully, and today it begins to rival the hollow-metal-tube system.[2]

The planar-transmission system constitutes an evolution of the coaxial system and operates in the *TEM* mode. This evolution is shown in Fig. 60, and field distribution
Fig. 70. Variation of shunt susceptance with diameter of post. Fiberglas G-6 dielectric, frequency 4,700 Mc.
Fig. 71. Variation of shunt susceptance with location of post.

is shown in Fig. 61.[3] Physically wide transmission lines of low characteristic impedance may be analyzed using the parallel-plate capacitance formula. For lines of 50 ohms and up, fringing effects play an appreciable role and Fig. 62 shows this. It is plotted for center conductors of zero thickness. This type of line is well adapted to printing techniques, and a complete line of circuit elements and components has been developed.

[3] Barrett, M., *loc. cit.*

Various groups have shared in the development of the planar-transmission system. Figure 63 shows three practically useful configurations.[1] Microstrip, shown on the left, has been used to realize a number of complex microwave circuits. It shows considerable dielectric losses and is thus not eminently suitable for long-line or high-Q filter applications. An analysis of the system is given by Deschamps.[2]

The sandwich and particularly the stripline, shown in the center and to the right in Fig. 63, permit construction of high-Q components since losses are mostly in the conductors. They are naturally more difficult to build.

In microstrip, *TEM*-mode propagation may only be assumed in a lossless system with dielectric of infinite width. Figure 64 shows, however, that field and power flow are in the dielectric near the narrow strip.
FIG. 72. Microstrip resonant section with transverse posts. Fiberglas dielectric. Insertion loss 1.4 db at center frequency.

37. Dielectric-image Lines. The millimeter-wave region is attracting much interest. Hollow metal wave guides with their dimensional correspondence to wavelength require an uncomfortable degree of precision in this range. Low-loss dielectric guides carry only a small fraction of the energy associated with the wave in the dielectric. The balance propagates in the regions around the dielectric. Although these regions measure several wavelengths the millimeter region permits physically realizable structures of this type.

In the dielectric, an HE_{11} or dipole mode offers low attenuation and a high degree of freedom from higher modes. Its phase constant is very nearly that of free space.[1] This seems reasonable since most of the energy travels through the space adjacent to the guide. This dipole mode possesses a plane of symmetry and may therefore

be operated in an image system. Figure 75 shows such a dielectric-image line in cross section and indicates the distribution of the E field. A metal ground plane of the width $2b$ carries a dielectric bead of semicircular cross section and $2a$ diameter.[1]

Components for dielectric-image-line systems have recently been developed. Several are shown by King[1] (see Figs. 76 to 78). While still in the early phases of development this system is expected to become very useful in the millimeter and submillimeter ranges.

[1] King, D. D., Properties of Dielectric Image Lines, *Trans. IRE*, **MTT-3** (2), 75, March, 1955. King, D. D., Circuit Components in Dielectric Image Lines, *Trans. IRE*, **MTT-3** (6), 35, December, 1955.

For right-angle bends, a reflector at exactly 45 deg and located at the intersection of the center lines of the straight sections, with sharply bent dielectric sections, yields much better match and lower losses than a gently curved line without the reflector. Figure 78 indicates cross-sectional field distributions for various cross sections of the dielectric bead. The maximum field occurs in the dielectric and is taken as the reference level. This figure indicates that the cross section of the dielectric bead is not very critical.

CAVITY RESONATORS

Conventional resonant circuits, consisting of a coil and capacitor, are hardly suitable at microwave frequencies, as the physical dimensions become too small and the losses by radiation may be considerable. At higher radio frequencies, sections of transmission line are used as circuit elements, and coaxial lines offer the particular advantage of minimizing radiation losses because the electromagnetic fields are completely enclosed within the outer conductor.

Coaxial line resonators are now generally included in the classification of cavity resonators, but the term did not come into general use until after it was realized that a hollow closed conducting box of arbitrary shape possessed electrical resonance properties similar to the conventional coil and capacitor circuit.[1] Rectangular, cylindrical, or spherical cavities may therefore be used at microwave frequencies to serve many of the same purposes that ordinary resonant circuits perform at lower frequencies, and in addition may possess an extraordinarily high efficiency. Qs in the order of many thousand are not uncommon. Moreover, all cavity resonators possess not one but an infinite number of resonant frequencies, analogous to the infinite number of transmission modes of a wave guide.

FIG. 79. Development of cavity resonator from a coil-capacitor circuit.

An illustration of how a cylindrical cavity may be developed from a conventional coil-and-capacitor circuit is given in Fig. 79. The coil reduces to a single turn of wire at higher frequencies; this wire is in turn paralleled by others to reduce the inductance and increase the resonant frequency, until finally a solid wall connects the capacitor plates, and the cavity resonator is formed.

With a cavity resonator, it is not possible in general to specify the exact inductance and capacitance of the equivalent resonant circuit. It is possible to specify, however, within limits of practical calculation the exact frequency of resonance for each of the resonance modes. Also the Q of a given cavity in a given mode may be uniquely defined. Finally, it is possible in many cases to specify the shunt impedance of a given cavity, once the path is determined along which the voltage shall be measured. In most instances, however, the choice of path is in some measure arbitrary.

38. Resonant Frequency. To calculate the resonant frequency of a cavity resonator, solutions to Maxwell's equations must be found which satisfy the boundary conditions imposed by the resonator. If the usual assumption is made that the cavity wall is a perfect conductor, the boundary conditions to be met are that no tangential electric field and no normal magnetic field exist at the surface of the cavity walls.

Under the above assumption, exact solutions are possible for resonators of simple geometrical shape. In practical cases, discrepancies between measured and calculated values for these simple shapes are extremely small, and usually attributable to mechanical imperfections in the cavity or to perturbations caused by the measuring device. A number of approximate methods of calculation have been developed which give more or less accurate answers for many more complex cavity shapes.

A principle of similitude may be applied to cavity resonators as follows: If all the linear dimensions of a cavity resonator are changed by a constant factor (and the resistivity of the walls changed by the same factor), the resonant wavelengths of all

[1] Hansen, W. W., A Type of Electrical Resonator, *J. Applied Phys.*, **9** (10), 654, October, 1938.

the normal modes in the cavity will be scaled by the same factor. The correction indicated in the parentheses is usually very small.

39. Resonator Q Values. The Q of a resonator in any given mode may be uniquely defined by the expression

$$Q = 2\pi \frac{\text{energy stored}}{\text{energy lost per cycle}} \tag{30}$$

If dielectric losses in the cavity resonator are neglected and if only losses resulting from conduction currents in the walls are considered, these losses are

$$\text{Energy lost per cycle} = \frac{\delta}{8} \int B^2 |d\sigma| \tag{31}$$

where δ = skin depth
B = magnetic field at wall of cavity
$d\sigma$ = element of area in cavity wall

The integral is carried out over the interior surface of the cavity. The energy stored in the cavity is

$$\text{Energy stored} = \frac{1}{8\pi} \int B^2 d\tau \tag{32}$$

with $d\tau$ an element of volume, and the integral carried out over the volume of the cavity. The Q of the cavity is then

$$Q = \frac{\lambda}{\delta} \frac{2}{\lambda} \frac{\int B^2 d\tau}{\int B^2 |d\sigma|} \tag{33}$$

It will be seen that Q is a dimensionless quantity. The above expression may be rewritten as

$$Q \frac{\delta}{\lambda} = \frac{2}{\lambda} \frac{\int B^2 d\tau}{\int B^2 |d\sigma|} \tag{34}$$

and the quantity $Q \frac{\delta}{\lambda}$ will be independent of frequency for a resonator of given shape and constant conductivity operating in a given mode. This quantity is sometimes known as the *form factor* of the cavity. The size of the resonator is inversely proportional to the frequency. As the skin depth varies as $\sqrt{\lambda}$, the Q of the cavity of given shape operating in a given mode will also vary as $\sqrt{\lambda}$, or inversely as $\sqrt{f}$.

For a nonreentrant resonator, the mean surface value of B^2 is approximately twice the mean value throughout the volume, and it can be said approximately that

$$Q \frac{\delta}{\lambda} \cong \frac{1}{\lambda} \frac{V}{S} \tag{35}$$

where V is the volume and S the bounding surface of the resonator, given in the same linear units as λ. For highly reentrant resonators, it is a better approximation to multiply the Q as given by Eq. (35) by a factor approaching 2. The form factor increases with increasing volume-to-surface ratio, and therefore large cavities which operate in one of the higher modes of oscillation will generally have higher Qs than smaller cavities operating in simpler modes at the same wavelength. Cavities which are highly reentrant have a low volume-to-surface ratio and are likely to have lower Qs than simpler shapes will give.

40. Shunt Impedance of Cavity Resonators. The shunt resistance, or shunt impedance at resonance, of a cavity resonator may be defined by

$$R_{sh} = \frac{\text{voltage}^2}{2 \times \text{energy lost per sec}} \tag{36}$$

where the voltage is the line integral of electric field along some reasonable path, usually the path along which the maximum value of voltage is developed. If the resonator is being driven by a beam of electrons, the path that is chosen in a calculation of shunt impedance is the path followed by the electron beam. The shunt impedance of a typical, nonreentrant cavity at a frequency of 3,000 Mc will be in excess of 1 megohm. If the cavity is reentrant, the shunt impedance will be lower, but values in excess of 100,000 ohms are typical for highly reentrant cavities such as are used in velocity modulation tubes at these frequencies.

If the wall conductivity of a given cavity is increased, both Q and the shunt resistance of the cavity will increase proportionally to the square root of the wall conductivity. Also, if a cavity of given shape is scaled in size to resonate at a different frequency, both Q and the shunt resistance will be inversely proportional to $\sqrt{f}$.

To say that a cavity has a high Q does not necessarily imply, however, that it also has a high shunt resistance, nor does a high shunt resistance imply a correspondingly high Q. It is possible to find cavity shapes in which a moderate Q is accompanied by an extremely high or an extremely low shunt resistance. A long cylindrical resonator operating in the $TM_{0,1,0}$ mode would have a high shunt resistance, and a reentrant coaxial resonator that is heavily capacitance-loaded would have a low shunt resistance.
FIG. 80. Rectangular prism cavity resonator.

CHARACTERISTICS OF TYPICAL CAVITIES

41. Rectangular Resonators. The characteristics of a rectangular prism resonator, illustrated in Fig. 80, are readily calculated by analytical methods. A resonant wavelength will be found in such a resonator when

$$\lambda = \frac{4}{\sqrt{\left(\frac{l}{a}\right)^2 + \left(\frac{m}{b}\right)^2 + \left(\frac{n}{z_0}\right)^2}} \qquad (37)$$

where l = number of half-wave variations of field along the x axis
m = number of half-wave variations of field along the y axis
n = number of half-wave variations of field along the z axis
l, m, n = 0, 1, 2, 3, . . . but not more than one may equal zero for fields to exist

If the three dimensions of the resonator are equal and if the resonator is a perfect cube, there will be a twelvefold degeneracy; *i.e.*, 12 different modes will have identical resonant frequencies. If the three dimensions are unequal, this will be reduced to a twofold degeneracy, which in general will be destroyed by any irregularities in construction.

Counting each of the degenerate modes as a separate mode, the number of modes, dN, in a range $d\lambda$ is

$$dN = 8\pi \frac{V}{\lambda_1^4} d\lambda \qquad (38)$$

where V is the resonator volume and λ_1 is the center of the wavelength band $d\lambda$. The number of resonant states, N, in a large rectangular prism resonator with resonant wavelengths greater than some minimum wavelength λ_2 is given approximately by

$$N = \frac{8\pi}{3} \frac{V}{\lambda_2^3} \qquad (39)$$

This approximate formula is quite accurate even for low N.

For a resonator in which $a = b$ and where $l = m = 1$ and $n = 0$, the formulas for resonant wavelength, Q, and shunt impedance are given in Table 5, page 6-51. For large cubical resonators, operating in a high mode of oscillation, the Q is given approximately by

$$Q\frac{\delta}{\lambda} = \frac{a}{2\lambda_0} \tag{40}$$

42. Cylindrical Resonators.[1] For circular cylindrical resonators, as illustrated in Fig. 81, the infinite number of resonant modes that exist may be divided into two classes, corresponding to the two classes of transmission modes in a wave guide.

1. *TE Modes.* The electric field in these modes is everywhere transverse to the axis, while the magnetic field has an axial component. The resonant wavelength of these modes is given by

$$\lambda = \frac{4}{\sqrt{\left(\frac{l}{z_0}\right)^2 + \left(\frac{2u_{m,n}'}{\pi a}\right)^2}} \tag{41}$$
Fig. 81. Circular cylindrical cavity resonator.

Each of these modes occurs when the resonator is effectively a section of a circular wave guide that is an integral number of $\lambda/2$ long for some TE mode of transmission in the wave guide. The term l gives the number of $\lambda/2$ along the resonator axis and must therefore be an integral number. No modes exist in which $l = 0$. If the $TE_{m,n}$ mode in a wave guide is the mode being excited in the resonator, $u_{m,n}'$ is the nth root of the equation

$$J_m'(u') = 0 \tag{42}$$

Some of the lower roots of this equation are listed in Sec. 4.

The Q of the resonator for some of the lower modes may be obtained from Fig. 82.

The circular electric modes in circular cylindrical cavities, identified by subscripts of the form $TE_{0,n,l}$, are noteworthy for their exceptionally high Q. For this reason, they are ideal for high-precision cavity wavemeters, and also for echo boxes, as discussed in subsequent paragraphs.

2. *TM Modes.* The second class of resonant modes in circular cylindrical cavities is characterized by a magnetic field that is everywhere transverse to the axis, while the electric field has an axial component. The resonant wavelength of these modes is given by

$$\lambda = \frac{4}{\sqrt{\left(\frac{l}{z_0}\right)^2 + \left(\frac{2u_{m,n}}{\pi a}\right)^2}} \tag{43}$$

As before, each of these modes occurs when the resonator is effectively a section of circular wave guide that is an integral number of $\lambda/2$ long, this time for some TM mode of transmission in the wave guide. As before l gives the number of $\lambda/2$ along the axis and must therefore be an integral number, but in addition modes exist in which $l = 0$, corresponding to no transmission mode in a wave guide. These modes have an electric field that is everywhere parallel to the axis. If the $TM_{m,n}$ mode in a wave guide is the mode being excited in the resonator, $u_{m,n}$ is the nth root of the equation

$$J_m(u) = 0 \tag{44}$$

Some of the lower roots of this equation are listed in Sec. 4.

[1] Wilson, I. G., C. W. Schramm, J. P. Kinzer, High Q Resonant Cavities for Microwave Testing, *Bell System Tech. J.*, **25** (3), 408, July, 1946. See also Kinzer, J. P., and I. G. Wilson, End Plate and Side Wall Currents in Circular Cylindrical Cavity Resonator, *Bell System Tech. J.*, **26** (1), January, 1947.

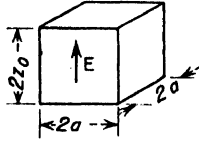
The simplest mode in a cylindrical cavity is the $TM_{0,1,0}$ mode. For this mode the characteristics are listed in Table 5.

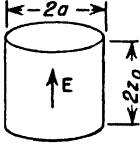
43. Spherical Resonators. The longest resonant wavelength will be found in a spherical cavity of radius a when

$$\lambda = 2.28a \tag{45}$$

and the next longest when

$$\lambda = 1.4a \tag{46}$$

The field configuration for these two modes is shown in Fig. 83. Values for Q and shunt impedance of the first mode are given in Table 5.




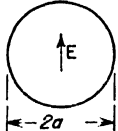


FIG. 82. Form factor of some of the lower modes in circular cylindrical resonators, from which Q may be determined.

44. Coaxial Line Resonators.[1] One type of coaxial line resonator is that shown in Fig. 84. The lowest *TEM* resonance in this cavity will be found when the cavity is $\lambda/2$ long. This resonant wavelength is given by $\lambda = 4z_0$. The Q of the cavity in this mode is

$$Q\frac{\delta}{\lambda} = \frac{1}{4 + \dfrac{2z_0}{b}\dfrac{1 + b/a}{\log_e b/a}} \tag{47}$$

[1] Barrow, W. L., and W. W. Mieher, Natural Oscillations of Electrical Cavity Resonators, *Proc. IRE*, **28** (4), 184, April, 1940. Some slightly misleading aspects of this paper are clarified by R. A. Kirkman and M. Kline, The Transverse Electric Modes in Coaxial Cavities, *Proc. IRE*, **34** (1), 33P, January, 1946.

Table 5. Characteristics of Simple Cavity Resonators Operating in the Lowest Mode of Oscillation

	Rectangular prism	Cylinder	Sphere
λ_0	2.828 a	2.61a	2.28 a
$Q\frac{\delta}{\lambda}$	$0.353 \dfrac{1}{1+\dfrac{a}{2z_0}}$	$0.383 \dfrac{1}{1+\dfrac{a}{2z_0}}$	0.318
$R\frac{\delta}{\lambda}$	$120\dfrac{z_0}{a} \dfrac{1}{1+\dfrac{a}{2z_0}}$	$144\dfrac{z_0}{a} \dfrac{1}{1+\dfrac{a}{2z_0}}$	104.4

and the highest Q is found when the diametric ratio is $b/a = 3.6$. The shunt impedance of this resonator is

$$R\frac{\delta}{\lambda} = \frac{60}{\pi}\frac{b}{z_0}\frac{\log_e^2 b/a}{1 + b/a}\,\frac{1}{1 + 2\dfrac{b}{z_0}\dfrac{\log_e b/a}{1 + b/a}} \tag{48}$$

The maximum shunt impedance is found when $b/a = 9.2$. Highest Q and highest shunt impedance require different values of diametric ratio, b/a. But neither shunt impedance nor Q is very critical to this ratio, as the Q will fall only to 78 per cent of its maximum value for $b/a = 9.2$, and the shunt impedance will fall only to 74 per cent of its maximum value for $b/a = 3.6$.

In addition to this lowest mode, resonant frequencies will be found whenever the cavity is an integral multiple number of $\lambda/2$ long, not only for the principal *TEM* mode, but also for any of the higher modes. None of these higher modes will give resonances unless the diameter of the line is sufficiently large. For the first of the higher modes
FIG. 83. Two lowest resonant modes in spherical cavity.

to be above cutoff and be a possible source of resonances, the arithmetic mean circumference of the line should exceed a full wavelength.

FIG. 84. Cavity resonator formed from a section of coaxial line shorted at both ends.

45. Capacitance-loaded Coaxial Line Resonators.[1] Resonators similar to the capacitance-loaded, coaxial line resonator shown in Fig. 85 are widely used in vacuum-tube u-h-f circuits. Klystron resonators are of this type in many instances, and disk-seal triodes are frequently employed with resonant circuits of this type.

Because of the relatively complex resonator geometry, accurate calculations of the resonant frequency and other characteristics are difficult to make, but approximate formulas are more readily developed.

Where the ratio of length to diameter of the cavity is large and the capacitance between the open end of the center conductor and the end of the cavity is small, the cavity will resonate when the inner conductor is approximately $\lambda/4$ long. As the capacitance at the open end of the center conductor becomes appreciable, the length of the center conductor for resonance becomes less. An approximate calculation of resonant wavelength which neglects the fringing fields at the capacitance gap gives for the resonant wavelength

$$\lambda = 2\pi \left(\frac{z_0 a^2}{2d} \log_e \frac{b}{a} \right)^{1/2} \tag{49}$$

The true resonant wavelength will always be greater than predicted by this formula, usually from 25 to 75 per cent greater. Accuracy will be best when the resonator is heavily capacitance-loaded.

For a reentrant resonator with considerable capacitance loading, the Q is given approximately by

$$Q\frac{\delta}{\lambda} = \frac{2z_0}{\lambda} \frac{\log_e b/a}{2\log_e \dfrac{b}{a} + z_0\left(\dfrac{1}{b} + \dfrac{1}{a}\right)} \tag{50}$$

where z_0, b, and a are the cavity dimensions as given in Fig. 85. The shunt impedance of this cavity is approximately

$$R\frac{\delta}{\lambda} = 60\pi\left(\frac{2z_0}{\lambda}\right)^2 \frac{\log_e^2 b/a}{2\log_e \dfrac{b}{a} + z_0\left(\dfrac{1}{b} + \dfrac{1}{a}\right)} \tag{51}$$

FIG. 85. Capacitance-loaded, coaxial line resonator.

More exact calculations show that a resonator with fixed gap spacing d and inner radius a will have its maximum shunt impedance when the toroidal cross section is approximately square, *i.e.*, when $z_0 - d = b - a$.

If the cavity is relatively long and of small diameter, so that losses in the end plates may be neglected, but has appreciable loading capacitance, the Q is given approximately by
[1] Examples of approximate techniques of calculation are given in the following papers: Hansen, W. W., On the Resonant Frequency of Closed Concentric Lines, *J. Applied Phys.*, **10** (1), 38, January, 1939. Mayer, E., Resonant Frequencies of the Nosed-in Cavity, *J. Applied Phys.*, **17** (12), 1046, December, 1946. Hahn, W. C., New Method for the Calculation of Cavity Resonators, *J. Applied Phys.*, **12** (1), 62, January, 1941. Motz, H., Calculation of the Electromagnetic Field, Frequency, and Circuit Parameters of High-frequency Resonator Cavities, *J. IEE*, **39**, Pt. III (25), 335, September, 1946.

$$Q\frac{\delta}{\lambda} = \frac{\log_e \dfrac{b}{a}}{\pi\lambda\left(\dfrac{1}{b}+\dfrac{1}{a}\right)}\left(\frac{\sin\dfrac{4\pi z_0}{\lambda}}{\dfrac{z_0}{\lambda}+\dfrac{\sin\dfrac{4\pi z_0}{\lambda}}{4\pi}}\right) \tag{52}$$

and the shunt impedance approximately by

$$R\frac{\delta}{\lambda} = \frac{\log_e{}^2 b/a}{\lambda\left(\dfrac{1}{b}+\dfrac{1}{a}\right)}f(\lambda) \qquad \text{ohms} \tag{53}$$

where $f(\lambda)$ is given in Fig. 86.

Important progress toward a more rigorous analysis of cavity resonators is described in the recent literature.[1]

46. Coupling to Cavities. To utilize a cavity resonator, it is usually necessary to couple it to a transmission line. This may be done in a variety of ways. The coupling may be magnetic by means of a small coupling loop which links some of the magnetic flux lines of the desired mode in the resonator. The amount of coupling will be proportional to the magnetic flux enclosed by the loop and therefore to a first approximation proportional to the area of the loop.

To provide electric coupling to a cavity, the center conductor of a coaxial line may be extended as a probe into the cavity and will couple to the cavity if there is a component of electric field for the desired mode tangent to the probe. The coefficient of coupling will increase with increasing probe length and will also be greater if the probe is located at a point of high electric field strength.

FIG. 86. The function $f(\lambda)$ used in Eq. (53) in the computation of shunt impedance of a capacitance-loaded coaxial line resonator.

Cavities may be coupled to wave guides by holes through the metal wall that separates the guide from the cavity. There will be magnetic coupling through a round hole if the magnetic field at the surface of the guide has a component parallel to the magnetic field at the adjoining surface of the cavity. There will be electric coupling if both guide and cavity have components of electric field normal to the common surface between them. The coefficient of coupling in both instances will be proportional to the third power of the hole diameter, if the wall is thin and the hole is small.

If a narrow slot is used instead of a round hole for coupling, the electric coupling will be small, but there may be appreciable magnetic coupling if there is a component of magnetic field in both guide and cavity parallel to the slot. Coupling between cavities and transmission lines by these various means is illustrated in Fig. 87.

When a cavity is coupled to a transmission line, the resonant frequency and Q of the cavity are affected by the coupled load, and there is usually some question as to

[1] Whinnery, J. R., and D. C. Stinson, Radial Line Discontinuities, *Proc. IRE*, **43**, 46, January, 1955. Stinson, D. C., Resonant Frequencies of Higher-order Modes in Radial Resonators, *Trans. IRE*, **MTT-3**, 4, October, 1955. Schelkunoff, S. A., On Representation of Electro-magnetic Fields in Cavities in Terms of Natural Modes of Oscillation, *J. Applied Phys.*, **26**, 1231, October, 1955. Tinkham, M., and M. W. P. Standly, The Excitation of Circular Polarization in Microwave Cavities, *Proc. IRE*, **43**, 734, June, 1955.

just where the lines of demarcation are between the cavity, line, and coupling circuit. For many purposes it is convenient to regard the resonant frequency of the cavity under these conditions as that frequency at which a minimum standing-wave ratio will be measured on the transmission line, when energy is fed into the cavity. This is the frequency at which free oscillations will occur in the circuit if the transmission line is terminated in its characteristic impedance.
FIG. 87. Various methods of coupling between transmission lines and cavities. (*a*) Electric coupling between coaxial line and cavity by probe. (*b*) Magnetic coupling between coaxial line and cavity by loop. (*c*) Magnetic coupling between rectangular wave guide and cavity by a hole in the common wall.

The amount which the cavity is loaded by the coupled transmission line may be determined by the standing-wave ratio at resonance in the line feeding the cavity. The following Qs have been defined which are applicable to this situation:

$$\text{Unloaded } Q = Q_0 = \frac{2\pi f \times \text{energy stored in cavity}}{\text{power dissipated in cavity}}$$

$$\text{External } Q = Q_e = \frac{2\pi f \times \text{energy stored in cavity}}{\text{power dissipated in load}}$$

$$\text{Loaded } Q = Q_L = \frac{2\pi f \times \text{energy stored in cavity}}{\text{power dissipated in load and cavity}}$$

The various Qs are then related by the following equations:

$$\frac{Q_0}{Q_L} = 1 + \beta \qquad (54)$$
$$\frac{Q_0}{Q_e} = \beta \qquad (55)$$

$$\frac{Q_e}{Q_L} = 1 + \frac{1}{\beta} \qquad (56)$$

FIG. 88. An electron beam coupled to a cavity.

The term β is equal to the voltage standing-wave ratio at resonance in the input transmission line, if the positions of the minimums of the standing waves at resonance coincide with the positions of the maximums when the cavity is detuned. If the standing-wave minimums at resonance coincide with the minimums when the cavity is detuned, β is the reciprocal of the standing-wave ratio measured at resonance on the input line.

Energy may be supplied to a cavity by an electron beam passing through the cavity. If the transit time through the resonator is short compared to a cycle, there will be power transferred from the beam to the cavity if the beam has an alternating component of current, *i.e.*, if the beam is in the form of bunches of electrons. These bunches
FIG. 89. Nomogram for calculating effect of humidity on resonant-line or cavity wavemeters.

may be formed either by velocity modulation action coupled with passage through a drift space, as in a klystron, or by the action of an alternating voltage applied to a control grid, as in a class C amplifier. The alternating voltage developed across the path of the beam will be equal to the product of resonator shunt impedance and the alternating component of beam current, provided the peak resonator voltage does not

exceed the beam voltage. A highly reentrant cavity, as shown in Fig. 88, is usually required to give an appreciable shunt impedance coupled with short transit time.
Fig. 90. Wavemeter cavity formed from section of coaxial line, shorted at both ends, of variable length.

If the transit time through the cavity is appreciable compared to a cycle, calculation of the power transfer is more difficult. It can be shown that a beam which is unmodulated when entering a cavity is capable of exciting oscillations in the cavity if the transit time through the cavity is of the proper value.[1]

47. Effect of Temperature and Humidity upon Resonant Frequency. The resonant frequencies of a cavity depend upon the physical dimensions of the cavity, and if these dimensions vary with changing temperature, the resonant frequencies will also change. If the cavity is constructed of a single metal, the percentage change in resonant wavelength for any mode will be equal to the percentage change in linear dimensions, which in turn will depend upon the temperature change and the expansion coefficient of the metal.

Fig. 91. Coaxial cavity wavemeter which is resonant when the center conductor is approximately λ/4 long.

The resonant frequencies of the cavity will also vary if the dielectric constant of the medium inside the cavity changes. If the cavity is not sealed, the changing dielectric constant of the air resulting from variations in temperature and humidity will cause changes in its resonant frequencies. These changes may be determined from the nomogram of Fig. 89.[2]

Fig. 92. Cavity wavemeter in which cavity is cross between λ/4 coaxial line resonator and a circular cylindrical resonator operating in the $TM_{0,0}$ mode.

48. Cavity Wavemeters. The extremely high Qs associated with cavity resonators make them ideal for use as wavemeters at microwave frequencies. The simplest type of cavity wavemeter, which is really a coaxial line Lecher wire system, is shown in Fig. 90. The cavity is a section of coaxial line, shorted at both ends, which is resonant when λ/2 long. The resonant frequency is varied by moving the shorting plunger at one end of the cavity to change the length of the cavity.

A second type of coaxial cavity that is widely used is shown in Fig. 91. This cavity is a λ/4 coaxial line, open at one end and shorted at the other. The resonant frequency is tuned by changing the length of the

plunger forming the center conductor. A variation of this design is shown in Fig. 92.[1] This cavity is really a hybrid between a $\lambda/4$ coaxial line resonator and a cylindrical resonator operating in the $TM_{0,1,0}$ mode, resembling the former when the plunger is extended, and the latter when the plunger is nearly withdrawn. This design offers advantages of higher Q coupled with a tuning characteristic that is nearly linear in frequency.

The $TE_{1,0}$ mode in circular wave guide has an exceptionally low attenuation, and wavemeters employing this mode have a correspondingly high Q. A typical wavemeter design employing this mode is shown in Fig. 93. The resonant frequency is changed by moving the shorting plate at one end of the cavity. This plate is not required to make contact with the cavity walls, as with this mode of operation there is no current flowing across this gap from the side walls to the end plates. A cavity operating in this mode is capable of giving spurious indications by resonating in modes other than the desired $TE_{0,1,1}$ mode, and these spurious indications must be eliminated by damping out the undesired modes. This may be done with the slug of lossy dielectric shown mounted behind the tunable end plate in Fig. 93. For the undesired modes, currents will flow from the side walls to the end plate, and fields will penetrate into the space behind the tunable end plate. Energy is absorbed from these fields by the lossy dielectric, and the Q of the undesired modes is correspondingly lowered. Fields from the desired mode do not penetrate into this space, and the Q is therefore unaffected by the lossy dielectric.
FIG. 93. High-Q cylindrical-cavity wavemeter operating in $TE_{0,1,1}$ mode. The lossy dielectric behind the tunable end plate eliminates spurious resonances.

49. Echo Boxes.[2] An echo box is a piece of test equipment used for over-all checks of radar systems. It consists of a high-Q cavity to which is loosely coupled a pickup antenna and also a crystal detector (Fig. 94). The echo box is placed in front of the antenna of the radar system, so that part of the energy radiated from the radar antenna during the transmitter pulse is picked up by the echo-box antenna and stored in the cavity in the form of oscillating electromagnetic fields. When the transmitter pulse is completed, this energy stored in the cavity will be reradiated through the echo-box antenna and detected by the radar receiver. The strength of this reradiated signal will decrease exponentially with time, and the length of time during which it can be detected by the radar receiver is a measure of the over-all performance of the radar system. This time, called the *ring time* of the echo box, depends upon the system tested.

For the rate of signal decay to be minimized, the Q of the echo-box cavity should be as high as possible. Two general types of cavities, tuned and untuned, are in use. The untuned cavity has dimensions large compared to a wavelength, and the various

[2] Gaffney, *loc. cit.* Also Green, E. E., H. J. Fisher, and J. G. Ferguson, Techniques and Facilities for Microwave Radar Testing, *Bell System Tech. J.*, **25** (3), 435.

resonant modes are therefore spaced so closely in frequency that one or more will be excited by the frequency spectrum of the radar transmitter. For this reason it is unnecessary to tune the cavity to the frequency of the transmitter. A typical untuned echo box for a frequency of 3,000 Mc will be a nearly cubical box, approximately a meter on each side. A perfect cube is avoided to prevent mode degeneracy, as discussed in Sec. 41.

A tuned echo box is smaller and for that reason more convenient to use, but it must be tuned to the frequency of the radar system. To obtain the requisite high Q
FIG. 94. Echo box being used for a check of the over-all performance of a radar system.

in a small cavity, the operating mode must be carefully chosen, and circular electric modes in circular wave guides are generally preferred. At 3,000 Mc, a cavity operating in the $TE_{0,1,1}$ mode has been found satisfactory with an operating Q over 40,000. At higher frequencies the ring time associated with a cavity of this design decreases rapidly, and it is therefore necessary to go to higher modes to get satisfactory performance. Much work has been done with cavities operating in the $TE_{0,1}$ mode in circular wave guide, but between 10 and 20 $\lambda/2$ long. These cavities give Qs well in excess of 100,000, but many troubles of interaction between the desired and undesired modes are encountered, which require very careful design to overcome.

CHAPTER 7

ELECTRON TUBES FOR LOW AND MEDIUM FREQUENCIES

By George D. O'Neill[1]

The present chapter reviews the basic principles on which low- and medium-frequency tubes are designed and made.

There are several classes of devices which, on this basis alone, would require inclusion if further restrictions were not imposed. Among these would be certain cold-cathode, gas-filled tubes, thyratrons, pool-type rectifiers, and television pickup tubes. Although some of these devices are of considerable interest, discussion of their characteristics and design is omitted largely on the ground that information in greater detail than is given in the manufacturers' ratings is of value to a much smaller group of readers than is the case for high-vacuum electron tubes.

Except in a few instances, methods of testing for the various characteristics of electron tubes are not described, primarily for the reason that the standards of the IRE[2] are widely available and more complete than could be given here.

The extent to which various topics in this chapter are pursued depends largely upon relative need. By way of example, thermionic emission is the concern of more engineers than is photoelectric emission; more engineers are concerned with the processing, design, manufacture, and use of receiving tubes than of transmitting tubes.

Finally, the manner of treatment of the various topics is, it is hoped, such as to be of maximum benefit to the average engineer, visualized as having a fair background in physics and mathematics but without the advantages of graduate training or the equivalent in experience. Discussion of vacuum techniques and certain "practical" aspects of tube making such as glass sealing, exhausting, and coating techniques have not been included for the reason that no amount of reading on such topics could take the place of learning by even a small amount of experience in a laboratory or factory.

ELECTRON EMISSION

The passage of electrons from a solid into a gas or vacuum is called *electron emission*. The mechanism by which emission occurs in most cases classifies the general phenomenon into the categories thermionic, photoelectric, secondary, and field emission.

1. Thermionic Emission from Metals. The kinetic energies of the free electrons in a metal are distributed in accordance with the Fermi-Dirac relation shown in Fig. 1. Here the abscissas represent kinetic energy on a linear scale with zero energy at the origin. The ordinates may be taken as the probability of finding an electron with the corresponding energy.

Curve *a* shows the energy distribution of the free electrons at absolute zero. It is noted that the most probable energy corresponds to the voltage E_1 and that there are no electrons having energies higher than this amount. At a higher temperature—say, 293°K or room temperature—the curve will look more like *b*; it is seen that a few electrons now have energies greater than E_1. Curve *c* represents the energy distribution at a still higher temperature.

The energy E_2 of Fig. 1 represents a critical level. An electron arriving at the surface of the metal may emerge from it if the surface-directed component of its energy

[1] Research Laboratories, Sylvania Electric Products Inc.

[2] Standards on Electron Tubes: Methods of Testing, *Proc. IRE*, **38**, Part I (8), 917, August, 1950; **38**, Part II (9), 1079, September, 1950.

is equal to or greater than E_2. If the surface-directed component is just equal to E_2, the electron emerges with zero initial velocity; if it is greater than E_2 the excess is the measure of the initial velocity upon emergence.
Fig. 1. Energy distribution of electrons in metals.

Since an electron may have maximum energy measured by E_1 volts at absolute zero, 0°K, the difference between E_2 and E_1 measures the amount of energy that must be added by heating. This energy difference $(E_2 - E_1)$ is equal to $e\phi$, where e is the electron charge and ϕ is called the *work function.*

Not all electrons having a surface-directed energy greater than the work function are emitted; a fraction $\bar{r}$ will be reflected from the surface.

The quantitative relation between these variables is expressed by the relation

$$I = A_0(1 - \bar{r})T^2\epsilon^{-b/T} \qquad (1)$$

where I = emission current per unit area

A_0 = constant having a theoretical value of 120 amp/sq cm per deg² for metals; experimental values are usually about half this figure

$\bar{r}$ = reflection coefficient

T = absolute temperature

The exponent b in Eq. (1) is a measure of the work required to remove an electron from the cathode and is proportional to the work function of the cathode, the relation being

$$b = \phi e/k \qquad (2)$$

where ϕ = work function, volts

e = magnitude of charge of electron

k = Boltzmann's constant

Expressed in practical units,

$$b = 1.16 \times 10^4\phi \quad \text{deg K} \qquad (3)$$

For most practical cases, therefore, the thermionic-emission density for metals may be taken as

$$I = 60T^2\epsilon^{\ 11,600\phi/T} \quad \text{amp/sq cm} \qquad (4)$$

when T is given in Kelvin or absolute degrees centigrade and ϕ is in volts.

Agreement between theory and practical results is usually satisfactory for metals, since a check on the value of ϕ from thermionic-emission data can be made by determining the long-wavelength limit of the photoelectric effect for the same cathode. With composite surfaces a number of factors commonly lead to inconsistencies, and recourse is generally had to statistical data where the ultimate objective is the design of an electron tube.

2. Tungsten Filaments. A brief summary of some practical thermionic cathode data is given below. These data are not, of course, intended to represent more than a small part of the information available in the complete literature.

Tungsten. Pure tungsten filaments were extensively used in early electron tubes. The ratio of emission to heating power is very low on account of the high work function of tungsten; consequently now only large transmitter tubes, where conditions of temperature and voltage are severe, employ tungsten.

The work function ϕ is given as 4.54 volts. Accordingly, the emission I_s in amperes per square centimeter may be calculated by Eq. (4) with the results tabulated for deg K, shown in the fourth column of Table 1.

* Melting point.

Thoriated Tungsten. The inclusion of a few parts per hundred of thorium oxide in tungsten wire permits, with proper processing, a considerable reduction in the work function. This processing consists in conversion of some of the thorium oxide to thorium metal which then diffuses outward, covering the tungsten. The emission from such a filament is given by Eq. (1), in which

$$b = 52{,}600 - 18{,}800\theta' \quad \text{deg} \tag{5}$$

where the factor θ' is related to θ, the fraction of the surface covered with a monatomic layer of thorium, as in Table 2; $A_0(1 - \bar{r})$ is taken as 60.2 amp/cm²/deg².

Table 2

θ	θ'	θ	θ'
0.00	0.00	0.5	0.790
0.05	0.127	0.6	0.863
0.1	0.240	0.7	0.920
0.2	0.430	0.8	0.960
0.3	0.579	0.9	0.988
0.4	0.697	1.0	1.000

It will be recognized that the temperature equivalent 52,600 in Eq. (5) is the value of b for pure tungsten. Therefore, for no thorium the work function is that of tungsten, 4.54 volts; for the fully activated surface, the work function will be about 2.9 volts.

3. Activation of Thoriated Tungsten Cathodes. Activation—the process of causing the thorium to diffuse out of the wire and coat the surface—is usually accomplished in one of two ways:

For *small filaments*, in which the operating current is of the order 0.25 amp or less, thorium oxide is reduced by raising the temperature of the filament to about 3000°K by the application of a voltage corresponding to two to three times that required for

normal operation. After about 30 sec the voltage is reduced to about 1.5 times the normal value and held for about 10 to 15 min to permit diffusion of thorium to the surface of the wire. The word "about" has been used advisedly, since some experimentation is usually in order before a satisfactory "aging" schedule for a particular design of filament can be specified.

For *large filaments*, as in transmitting tubes, the thorium oxide is not sufficiently reduced by the heat-treatment described above; consequently resort is had to carburizing, in which the filament is glowed at high temperature in the presence of a hydrocarbon gas such as acetylene at very low pressure (or in a heavier compound diluted with hydrogen at atmospheric pressure). It is usually preferred that the pressure of the gas be restricted to an amount just sufficient to cause penetration of the carbon to the desired depth; a safer practice is to admit a still lower quantity and remove the resultant hydrogen before more acetylene is admitted. Carburization in the presence of an excessive amount of gas frequently results in uneven penetration and excessive brittleness. The acetylene must be highly purified and entirely free of oxygen or water vapor. Ordinarily, the carburization is carried to the depth representing about 20 per cent of the cross-section area. In this process the outer shell of the filament is converted to a very brittle carbide of tungsten having high electrical resistivity. During carburization the thorium oxide is reduced to metallic thorium which may be diffused to the surface by an aging schedule similar to that described for the small filaments.

4. Properties of Pure and Thoriated Tungsten Cathodes. Column 5 of Table 1 gives the emission of pure and thoriated tungsten. Pure tungsten filaments are ordinarily operated at temperatures of 2500 to 2570°K, thoriated tungsten at 1900 to 2000°K.

Table 1 provides data for the design of a tungsten filament operating in vacuum. Excluding second-order effects, such as temperature of the surroundings and the variation in temperature along the filament, the variables will be

L = length of filament
E = filament voltage
I = filament current
ρ = resistivity
η = radiation intensity
r = radius of wire
d = diameter of wire

Formulas have been published for corrections due to cooling of the filament by the lead wires and hooks. Since the complete data necessary for precise determination of these corrections are seldom available, it is generally preferable, for ordinary computations, to follow a rule of thumb. This is simply to observe, in a sample or similar tube, the amount of filament which operates below visible incandescence and to consider that this part has zero resistance while the remainder has uniform resistance per unit length. The hot part of the filament is computed and the parts cooled by leads and hooks then added to give the final length. In the paragraphs to follow, L means the length of the hot part of the filament.

The hot resistance of the filament will be taken as the quotient of total filament voltage E by filament current I, and is related to the resistivity and dimensions by

$$E/I = \rho L/\pi r^2 \quad \text{ohms} \tag{6}$$

With the filament heated by power EI, the radiation intensity η, or power radiated per unit area, is

$$\eta = EI/2\pi rL \tag{7}$$

Since Table 1 gives ρ and η for centimeter units, L and r will be expressed in centimeters and the η will be in watts per square centimeter.

From Eqs. (6) and (7), the current and voltage of a wire 1 cm long and 1 cm in diameter may be computed for the temperatures given in the table, using the corresponding values of ρ and η. These values, I' and E', are given in the last two columns of the table. For values of I' and E' at temperatures intermediate between those

given, interpolation between the next higher and lower values yields results which are sufficiently accurate for most purposes. Then, for a wire of any other diameter d and length L operating at the same temperature, the current I will be

$$I = I'd^{3/2} \quad \text{amp} \tag{8}$$

and E will be

$$E = E'L/d^{1/2} \quad \text{volts} \tag{9}$$

In practice, the temperature of a wire having known dimensions is determined by computation of I' from current and diameter or of E' from length, voltage, and diameter. The temperature is then found from the table. In design, the length, voltage, and temperature are likely to be specified, in which case the diameter will be obtained from Eq. (9) by substituting the value of E' corresponding to the desired temperature. This diameter is then substituted into Eq. (8) with the corresponding value of I' to obtain the required current.

The constants of Table 1 apply only to clean tungsten or thoriated tungsten; hence the values of η, E', and I' do not apply to the heater wire of an indirectly heated cathode. However, Eq. (6) does apply in any case and is of use in computing the temperature of heater wire, when the design is achieved through cut-and-try methods. Here ρ is determined from voltage, current, and dimensions of the experimental tubes. The final tube should be so designed that the operating temperature of the heater does not exceed about 1450°K. Temperatures in excess of this value are apt to result in burnout trouble during exhaust or aging and may result in early failure of the heater.

It is difficult to measure with the degree of accuracy required the average diameter of a small tungsten wire when the wire is to be used in an electron tube or incandescent lamp, and recourse is had to the weight as measured by a sensitive torsion balance. Except for large sizes, the wire is commonly purchased and specified in terms of its weight in milligrams for a 200-mm length, the tolerance being specified—commonly 2 per cent. Table 3 gives the data required for the conversion of diameter in millimeters and mils (thousandths of an inch) to weight in milligrams per 200 mm.

5. Carburized Filament Design. In designing a carburized filament, it may be considered that the electron emissivity is the same as for the uncarburized thoriated wire. The resistance depends on the depth of carburization. As an approximation, the carburized portion may be taken to have infinite resistivity; *i.e.*, in the computations the resistance is taken on the basis of the uncarburized core while the radiation is taken for the original diameter. At the normal operating temperature of 1900 to 2000°K, the radiation intensity of the carburized wire is about 20 per cent greater than for clean wire at the same temperature. Thus, when the wire is 20 per cent carburized, a given current heats both to approximately the same temperature, the voltage being about 20 per cent greater for the carburized filament.

6. Oxide-coated Cathodes. The oxide-coated or Wehnelt cathode comprises a base metal such as nickel, tungsten, or one of a large number of alloys, coated with the oxides of barium and strontium or of barium, strontium, and calcium. There are numerous other types of coated cathodes, but their commercial importance is small relative to that of the BaO-SrO variety at the time this is written.

The electronic nature of an oxide is quite different from that of a metal; consequently the rather simple model of an emitter discussed in Sec. 1 must be considerably altered if a useful picture of the mechanism of electron emission from a coated cathode is to be obtained.

In Eq. (1) the quantity A_0 is derived on the basis that there are as many "free" electrons in the metal as there are atoms. The oxide coating of a thermionic cathode is an n-type semiconductor, in which conduction and emission are made possible by electrons "donated" by the ionization of impurities. These impurities may be chemical in nature, such as barium atoms not occurring as a normal point in the crystal lattice, or they may be defects such as vacancies in the latter. Consequently the number of conduction electrons in a crystal or grain of coating is far smaller than

the number of atoms. The result is that a term such as A_0, if used in connection with an oxide-coated emitter, is not a constant but depends on the composition, condition, and temperature of the coating.

Furthermore, the meaning of the term b, or $\phi e/k$, as used in Eq. (1), is not quite the same as one obtains from Fig. 1. An explanation of the concept of work function as applied to a semiconductor is beyond the scope of this book, but it should be pointed out that the net effect, from a practical point of view, is that the thermionic current obtainable from a coated cathode varies inversely with a power of the work function about as indicated by the equation. In a properly prepared, well-aged coated cathode, the work function $e\phi$ has a value of about 1.0 to 1.05 electron volts as compared with 4.54 for tungsten and 2.9 for thoriated tungsten; it is this fact which explains why the emission is so much higher at the same temperature.

In the case of receiving tubes employing indirectly heated cathodes, the power supplied by the heater is usually about 2.75 to 3.0 watts per sq cm of cathode area; in high-vacuum rectifiers it is higher, sometimes as great as 4.0 watts per sq cm to provide for the high peak currents frequently required.

Table 3. Weight and Diameter of Tungsten Wire

Weight, mg/200 mm	Diameter, mm	Diameter, mils	Weight, mg/200 mm	Diameter, mm	Diameter, mils
1	0.01830	0.72	32	0.1035	4.08

30	0.1002	3.95	200	0.2589	10.18
31	0.1018	4.01			

7. Emission Efficiency. It is difficult to decide what one would call an "average" oxide-coated cathode. On the basis of usual experience, a fair comparison might be made of the emission efficiencies—the quotient of emission current in amperes by heating power in watts—between the three principal types of thermionic cathodes. The quantities given are taken at the ordinary level of emission density of an oxide-coated receiving tube cathode.

Emitter	I_s/sq cm	Watts/sq cm	I_s/watt
Oxide-coated	0.10	2.75	0.0364
Thoriated tungsten	0.10	8.0	0.0125
Tungsten	0.10	55	0.0018

When the emission is measured by applying short pulses of voltage, for example, 1-μsec pulses at a repetition rate of 1,000 per second, the peak value of emission from a well-activated oxide-coated cathode may be ten to one hundred times larger than the figure given above.

In designing an indirectly heated cathode for general-purpose and receiving tubes, it is generally desirable to make the ratio of length to diameter as great as possible, since end loss is then low and clearance between cathode and the next nearest electrode is maximum. On the other hand, provision must be made for insertion of the heater, and the length-to-diameter ratio must not be so great that bending or bowing of the cathode is likely to be serious. In practice, the ratio is generally about 25.

8. Flat or Ribbon Filaments. Where a cathode with a flat or nearly flat surface is required, such as in a cathode-ray tube or others in which the electron stream is formed into a cylindrical beam, the heater-power efficiency is low compared with that of a cylinder coated on the side, although this is frequently of minor interest. Where a new design is required, life tests are commonly made over a range of heater power, and the heater current rating is selected on the basis of life test results.

For the directly heated cathode, the design of a filament is made on the basis of performance records of tubes using the same material. Knowing the dimensions of the filaments of these tubes and the voltage and current for satisfactory life, the values of ρ and η are computed. The new filament, if round, may be computed as for the tungsten wire; corrections for the cooling effect of the leads and hooks are applied in the same manner.

The use of a ribbon filament provides an additional degree of freedom in choice of dimensions or voltage or current, since the surface area may be varied without changing the area of cross section.

The relations corresponding to Eqs. (6) and (7) for the ribbon filament will be

$$\rho = abE/IL \qquad \text{ohms} \tag{10}$$

$$\eta = EI/2(a + b)L \qquad \text{watts/sq cm} \tag{11}$$

where a and b are the width and thickness of the ribbon.

From the data on known or experimental tubes, the values of ρ and η are computed for the conditions that have been shown to give best results for life test. Then when values of length, current, and voltage are specified, the other dimensions will be

$$a = \frac{EI}{4\eta L} + \frac{1}{2}\sqrt{\left(\frac{EI}{2\eta L}\right)^2 - \frac{4\rho LI}{E}} \qquad \text{cm} \tag{12}$$

$$b = \frac{EI}{4\eta L} - \frac{1}{2}\sqrt{\left(\frac{EI}{2\eta L}\right)^2 - \frac{4\rho LI}{E}} \qquad \text{cm} \tag{13}$$

Since the thickness b is important and is the difference between two quantities apt to be nearly alike, computation should be carried out by the use of log tables in which the values of the logarithms are given to at least six digits. The result is conveniently

checked by substitution in Eq. (9). A negative or complex solution indicates the values chosen for E or I are too small, or that L is too great. In the practical case, the ratio a/b is desirably greater than 3 and less than 15.

Since ribbon filament is ordinarily made by rolling a round wire, the thickness is apt to be somewhat variable across the width. For this reason, ribbon filaments are ordinarily specified in terms of width (mils) and weight (mg/200 mm) to ensure against wide variations in current and temperature.

9. Preparation of Cathodes. The base material, whether it is wire, ribbon, or an indirectly heated cathode, is thoroughly cleaned by solvent materials such as dichlorethylene, then heated in a hydrogen atmosphere to a temperature of about 1000°C before coating. The coating is usually applied in one of three ways:

Bench coating consists in passing the wire or ribbon alternately over revolving wheels in a cup of coating, then through an electric furnace. The coating is thus built up in several layers. The carbonates are suspended in a solution of barium nitrate, the nitrate serving as a temporary binder. The furnace is supplied with a stream of carbon dioxide.

Spray coating consists in spraying the coating suspension on the ribbon or cathode with a spray gun, nitrocellulose being used as a binder. The desired texture of the coating is achieved through adjustment of nozzle, air pressure, and distance between nozzle and cathode.

Electrophoresis consists in applying the coating to the cathode by passing the wire through, or dipping the cathode into, a suspension of the coating and applying a strong electric field between cathode and metallic container.

In coating the cathode, the active materials are in the form of carbonates which are broken down to the oxides during the exhaust process. These carbonates, usually of barium and strontium, are ordinarily prepared especially for the purpose. Many of the larger tube-manufacturing firms prepare their own carbonates, while others purchase them from chemical supply houses in a form especially adapted to this work. The barium and strontium carbonates—sometimes calcium carbonate is also a constituent—are precipitated together from a hot solution of the nitrate by the addition of a solution of ammonium carbonate, sodium carbonate, or sodium bicarbonate, then washed and calcined. The temperature and concentration of the solution are closely controlled to produce crystals of the proper form; these crystals ordinarily have a diameter of a few microns.

10. Coating Suspensions. The composition of the suspension will depend upon the method of coating, the size of the wire, and the intended use of the cathode; the experience of the process engineer is also an influencing factor. For this reason, the coating formulas given below merely illustrate the way in which such suspensions are compounded; they are, however, practical for use in making experimental tubes.

1. Bench-coating formula:
   - 1,000 g carbonate
   - 1,000 cc distilled water
   - 100 g barium nitrate (decrease for wide ribbon)
2. For use in spray gun:
   - 575 g carbonate
   - 1,000 cc amylacetate
   - 20 g nitrocotton
3. Electrophoretic suspension:
   - 50 g carbonate
   - 5 g barium nitrate
   - 1,000 cc amyl acetate
   - 63 g nitrocotton

In all cases the suspension is ball-milled for a minimum of 12 hr to ensure complete separation and wetting of the individual particles. In using formula 1, it is necessary to heat the wire to a temperature high enough to fuse the nitrate or to convert it to

the carbonate. In the other cases, care is taken to ensure thorough evaporation of the amylacetate or other solvents. Plasticizers are frequently added in small proportions to give a degree of flexibility to the coating when nitrocotton is used as the binder.

11. Exhaust and Aging of Coated Cathodes. During the exhausting of the tube, the carbonates are broken down to the oxides by the application of heat, the reaction being summarized by the chemical formula

$$BaCO_3 \rightarrow BaO + CO_2$$

At atmospheric pressure the reaction does not proceed very far owing to equilibrium between the carbonate, oxide, and carbon dioxide; at exhaust the carbon dioxide is continuously removed, permitting the reaction to go to complete breakdown of the carbonate.

After the tube has been sealed off, it is ordinarily aged. The cathode is heated by the application of a heater voltage higher than normal. This may be as great as two to three times normal operating value, followed by a second step in which the heater voltage is held at about 150 per cent of normal with the cathode passing a thermionic current of about 100 ma per sq cm. The emission current is usually limited by an incandescent lamp ballast in the plate circuit. The time required for aging may be a few minutes for the first step and 10 to 20 min for the second step. Aging schedules vary widely depending upon such factors as the type of tube, the exhaust schedule, coating texture, and the composition of the base material. Their specification is ordinarily the result of cut-and-try experimentation.

FIG. 2. L-type cathode.

12. Base Materials. The base or core material used in most coated cathodes is nickel. Usually the nickel contains impurities which serve to liberate free barium at the interface between base and coating by reacting with barium oxide. The barium, in trace amounts, is required for activation of the coating. For filamentary cathodes, alloying materials are also added to improve the mechanical properties of the wire or ribbon such as hot strength.

The impurities in nickel that serve to produce free barium by interaction are silicon, magnesium, titanium, aluminum, and sometimes one or more other elements. Silicon is a very active reducing agent, but it forms a highly insulating compound, barium orthosilicate, at the interface and this produces an adverse influence on the performance of the tube. Consequently, the silicon content is usually held at as low a percentage as possible.

Cathode nickel, or nickel, alloys are commonly classified as *active*, *normal*, or *passive* according to rapidity or ease with which activation of the coating takes place. There is no sharp line of demarcation between them. An active alloy commonly contains 1 per cent or more of reducing impurities; a normal alloy usually has less than 1 per cent, while the impurity content of a passive alloy is negligibly small. In aging, and during life, the impurities diffuse to the surface of the core where reaction with barium oxide takes place, and as the concentration of reducing impurities in the nickel approaches zero the electron emission usually drops below a useful value.

13. Dispenser Cathodes. A dispenser cathode consists essentially of an emitting surface supplied with an activating material from a reservoir, and a heater element as shown in Fig. 2. Best known is the "L" cathode, in which the active part of the cathode consists of a porous tungsten plate *A* covered by barium. The cylinder *B* into which all parts are assembled is commonly made of molybdenum, the heater *C* is alundum-covered tungsten wire, and the reservoir *D* is filled with (Ba, Sr)CO_3 or
the triple carbonate. When the tube is exhausted, the carbonate is reduced to the oxide.

Operation is, however, different from that of the ordinary cathode. The oxide in the reservoir is partially reduced with the liberation of a small amount of free barium; the latter migrates through the pores of the plate to the top surface. The work function of this cathode is usually about 1.60 to 1.65 electron volts, which is taken to mean that the surface of the tungsten is oxidized and almost completely covered by a monatomic layer of barium. Since the work function is higher than that of the ordinary coated cathode, dispenser cathodes must be operated at a higher temperature to obtain the same emission. The dispenser cathode is of special interest in devices requiring a high current density from a small area of the cathode, especially where ion bombardment is severe enough to ruin a coated cathode.

A modification of the dispenser cathode just described is the impregnated cathode, in which the reservoir *D* is omitted. Activating materials, commonly a mixture of normal and basic barium aluminates, or aluminates and carbonates, are deposited between the grains of the porous tungsten plate.

14. Matrix Cathodes. A matrix cathode is in some respects similar to the dispenser cathode in that the activating material is placed in, instead of on, the emitter. Powdered nickel is used as the base, and materials such as $(Ba,Sr)CO_3$ are compacted with the nickel. Alternatively, the nickel may be sintered to form a porous body, and the carbonates then precipitated within the interstices.

It is indicated by measurements of emission vs. temperature that a fully aged matrix cathode has a work function of about 1.05 to 1.10 electron volts; consequently it is assumed that the surface is covered with BaO or (Ba,Sr)O. Such cathodes have limited application and were still in the development stage when this book was published.

15. Testing Thermionic Emission. The thermionic-emission properties of a tube are measured in a number of different ways, the choice being determined by the type of tube or the purpose of the test. A number of these tests will be described briefly. In most cases all electrodes except cathode are tied together at the socket to form a composite anode, and the anode current is noted under conditions which may be specified.

Ideally, the (composite) anode current of a tube should increase with the three-halves power of the anode voltage, when the cathode temperature is constant, until temperature-limited emission is reached. From this point the current should increase only gradually as the field at the cathode is increased. In the actual case, especially with coated cathodes, it is often difficult or impossible to ascertain the point at which the transition from space-charge-limited to temperature-limited current occurs because of lack of uniformity in the temperature and emission constants of the cathode. Results are more meaningful if plotted as a Schottky line from which the true value of emission may usually be inferred.

The Schottky relation shows the manner in which the electron current is enhanced when the field is accelerating throughout the cathode-anode region. Here the total current I for ideal conditions is

$$I = I_0 \epsilon^{e\sqrt{-eF}/kT}$$

where F = electric field at cathode surface; I_0 = normal emission at $F = 0$; e = electron charge; k = Boltzmann's constant; T = temperature of cathode in absolute degrees.

This expression can be written $\ln I = \ln I_0 + e\sqrt{-eF}/kT$. When converted to common logarithms with the constants evaluated the result is

$$\log I = \log I_0 + (1.9/T)\sqrt{-F}$$

in which the current is expressed in amperes/cm² and the field in volts/cm. In most cases the emission is too high to test at normal cathode temperatures; hence pulse techniques are used. If the true temperature and field are not known, one may still

determine emission to a satisfactory degree of accuracy by taking the above expression in the form $\log I = \log I_0 + K\sqrt{e_p}$ in which K is a constant whose value need not be known and e_p is the plate voltage. If $\log I$ is plotted against a number of values of e_p the curve, at low values of plate voltage, is the three-halves-power relation; at high values of plate voltage the current increase, which is much less than in the space-charge region, is due mostly to the effects described by the Schottky relation. Therefore, if the curve in the Schottky region is extrapolated to $e_p = 0$, the intercept on the vertical axis gives the logarithm of the normal emission of the cathode.

For tubes having coated cathodes, care must be taken to avoid overheating. In many cases the emission may fall because of the decomposition of impurities on the anode so that materials poisonous to the cathode are released. For these reasons, approximation methods are frequently employed.

Some direct emission tests are as follows:

1. For small tubes having tungsten filaments, the emission current is measured at rated filament voltage and with the composite anode voltage at or near the value required to produce temperature-limited emission. Care must generally be exercised in keeping the time of test to a minimum to avoid overheating the electrodes.

2. For small tubes having coated filaments or coated, indirectly heated cathodes, the composite anode voltage is commonly set at a value which, in a well-activated tube, produces an emission current of approximately 200 ma per sq cm of emitter surface. The test must not be too long continued, although, for purposes of quality control, it is made for a long enough time–say 3 to 10 sec—to ensure that the emission is reasonably stable.

FIG. 3. Flection-point emission. Line a is hypothetical curve of space-charge current plotted against composite anode voltage. In the actual case the current is limited by emission line b. Tangent point x is taken as flection-point emission.

3. Where a very high degree of cathode activity is required and where the application of a voltage sufficiently high to result in a current near the temperature-limited value would result in serious injury to the tube, the anode voltage is pulsed at a relatively low duty cycle.

4. For many purposes, the "flection-point" emission is taken as a criterion of cathode activity. The flection point is defined as the point on the diode characteristic (current plotted against composite anode voltage) at which the second derivative of current with respect to voltage reaches its maximum negative value. This point is often referred to as the "knee of the curve." Although not rigorous, it is conveniently taken as point x, Fig. 3, the point of tangency between the diode characteristic and a straight line through the origin. Data may be taken point by point or by means of a cathode-ray oscillograph.

Indirect checks depend for their value upon the increase in emission with temperature, the total emission or tube performance being measured at a cathode temperature lower than normal. Two such checks will be described.

1. In tubes having filamentary cathodes that might be injured by the passage of a relatively high emission current, the check consists in measuring the filament voltage required for a substantially temperature-limited emission current of a specified

magnitude. For such a test the current will ordinarily be approximately that of the total cathode current under ordinary operating conditions.

2. For large transmitting tubes, an indirect emission check consists in testing the power output of the tube operating as a self-excited oscillator with standard voltages, then reducing the filament voltage until the power output is decreased to a specified fraction of the original value. The filament voltage reading under this condition then constitutes an indirect check upon emission. The value of such a check depends, to a considerable degree, upon judicious choice of circuit conditions and is applicable only in comparing individual tubes of the same type.

The cathode heating time is related to emission testing and will be mentioned here. Conventionally, this is the time which elapses between application of rated filament or heater voltage and the attainment of a cathode current such that its time rate of change is maximum, corresponding approximately to point x in Fig. 3. The primary of a transformer is placed in the cathode circuit with its secondary shunted by a microammeter; maximum rate of change occurs when the reading of the microammeter reaches maximum.

16. Photoelectric Emission. The energies of the conduction electrons of a solid material may be raised to a magnitude sufficiently high to permit their emergence from the body by means of radiation without heating. When emission occurs through the agency of radiation, usually within or near visible wavelengths, the emission is classified as *photoelectric emission*, the emitter is a *photocathode*, and the electron tube, whether gas-filled or vacuum, employing a photocathode is a *phototube*.

For what one might loosely call "white light," the magnitude of the photoelectric current for unit emitting area is proportional to the intensity of the light falling upon the photocathode and depends upon the work function of the surface in much the same manner as in the case of thermionic emission. On the other hand, the magnitude of the current also depends upon the color composition of the incident light for the reason that the energy which the light may give to an electron is inversely proportional to its wavelength. For a given emitter there will be a maximum wavelength, called the *threshold wavelength*, at which photoelectric emission is obtained; for shorter wavelengths the excess energy imparted to the escaping electron beyond that required to overcome the surface forces will be the kinetic energy the electron will have upon emergence. Quantitatively stated,

$$hc/\lambda = \phi e + mv_0^2/2 = h\nu \qquad (14)$$

where h = Planck's constant
c = velocity of light
λ = wavelength of radiation
ϕ = work function of photocathode, volts
e = electron charge
m = mass of electron
v_0 = velocity of electron upon emergence[1]
ν = wave frequency = c/λ in air or vacuum

The threshold wavelength is, therefore, the wavelength at which the second term of Eq. (14) just becomes zero. When the constants are evaluated in practical units and the work function ϕ is expressed in volts, the threshold wavelength λ_0 is given by

$$\lambda_0 = 12{,}395/\phi \quad \text{A} \qquad (15)$$

where the wavelength is measured in angstrom units, A = 10^{-8} cm.

As an example, if a photoelectric current is to be obtained which is sensitive to all the visible colors, and the limit of visibility is taken as 7000 A at the red end of the spectrum, the work function of the photocathode must be not greater than 12,395/7,000 = 1.77 volts. Many phototubes have their long-wave limit extending well into the infrared region. These tubes are not, however, to be confused with the

[1] The velocity v_0 will be greater by a small amount when the energy before excitation is added to both sides of the equation.

infrared cells such as the thallous sulfide type which are sensitive at wavelengths from within the visible range to and beyond 12,000 A.

While Eqs. (14) and (15) are intended to be rigorous only at absolute zero, the result is not greatly different at room temperature for the reason that the chance that a given electron shall be excited by the radiant energy appears to be independent of the energy it already had. Reference to Fig. 1 shows that the average energy is not greatly altered as the temperature is raised.

Most photoelectric cathodes exhibit a spectral selectivity such that the maximum response at a given level of incident radiant energy is obtained at a wavelength of or fairly near $2\lambda_0/3$. In the case of thin composite surfaces, such as those comprising an oxidized silver base upon which an alkali metal such as cesium or rubidium is deposited, two and sometimes three maxima are found, each being characteristic of an element or compound subjected to the radiation.

The "complete" photoelectric emission is expressed by an equation identical in form with that for thermionic emission. If the photoelectric cathode is exposed to the total thermal radiation from a black body at temperature T, the total photoelectric current for clean metals varies with T in accordance with the relation

$$I = A_1 T^2 \epsilon^{-h\nu_0/kT} = A_1 T^2 \epsilon^{-b_0/T} \quad \text{amp/sq cm} \tag{16}$$

in which A_1 is found to have values usually of about 10^{-10} to 10^{-9} amp per sq cm per deg^2 and $\nu_0 = c/\lambda_0$. The numerical value of b_0 is $1.16 \times 10^4 \phi$ deg as in the case for thermionic emission. This could be expected since the work ϕe done by the electron in leaving the cathode is the same regardless of whether its energy within the body is of thermal or photonic origin.

17. Photocathodes. The choice of a photoelectric tube depends, naturally, upon the use for which it is intended. The best guides in the choice of tube are the catalogues or handbooks of the most reliable manufacturers of such devices. The brief description to be given of some kinds of phototube cathodes is intended only for the general reader.

Of rather specialized interest are solid metal cathodes or cathodes coated to a relatively great thickness—*e.g.*, 100 or more atomic diameters—with metals having relatively high work function, such as zirconium, tantalum, or thorium. These are of interest in the measurement of ultraviolet light and usually are mounted in bulbs transparent to the desired regions of ultraviolet or employ quartz windows. Chemical cleanliness of the materials is of greatest importance; proper bulb baking and outgassing by induction heating are required for reasonably reliable results.

The sensitivity of some of these surfaces may be considerably enhanced and the long-wave limit λ_0 raised by passing a glow discharge between cathode and anode in the presence of hydrogen. This is preferably done after outgassing, the hydrogen being then pumped out before the tube is sealed off. Gases other than hydrogen, *e.g.*, sulfur vapor, have been tried with success.

Of greater interest are the photocathodes produced by the deposition of thin films of certain alkali metals upon a solid metal support. Because of the low work function of these surfaces, some of them are sensitive in the visible regions of the spectrum. A summary of features of present interest concerning some of these surfaces is shown below, the values given being approximate.

Surface	λ_m, A	λ_0, A
S-1 (commonly Co-O-Ag)	8,000	12,000
S-3 (commonly Rb-O-Ag)	4,300	9,000
S-4 (commonly Cs-Sb)	4,000	7,000
S-5 (commonly Cs-Sb)*	3,400	7,000
S-8 (commonly Cs-Bi)	4,200	8,000

* In ultraviolet transmission bulb.

λ_m is wavelength for maximum sensitivity; λ_0 is long-wavelength limit.

Among the most useful commercial photocathodes, from the standpoint of sensitivity, is the Cs-CsO-Ag emitter. Although the maximum sensitivity of this surface does not correspond to that of the human eye—none of them do—its performance under tungsten or daylight illumination is of considerable use in commercial devices. It consists essentially of a well-cleaned silver support which, during exhaust, is outgassed, then oxidized by the passage of a glow discharge in oxygen. Care must be exercised in obtaining the proper depth of oxidation, the progress being observed by watching the subtractive interference color changes. The uncombined oxygen is then removed and cesium distilled into the bulb, care being taken to admit only as much cesium as is required to produce the proper sensitivity.
FIG. 4. Average response of commercial photocathode surfaces compared with that of the average human eye.

The response characteristics of some commercial phototube surfaces are shown in Fig. 4, wherein the average spectral response is compared with that of the average human eye. Relative sensitivities for each curve are plotted against wavelength for equal values of radiant flux at all wavelengths at the photosurface except for the S-5 photocathode, which is plotted for constant flux outside the bulb.

18. Multiplier Phototubes. A multiplier phototube comprises essentially a photocathode, an anode, and one or more dynodes[1] sealed in an evacuated transparent envelope or an envelope having a transparent window. Commercial multiplier phototubes commonly have a sensitivity of 5 to 10 μa per microlumen. Cesium-bismuth and cesium-antimony photocathodes are commonly used.

In operation, the first dynode is maintained at a potential positive with respect to the photocathode, and each succeeding dynode is positive with respect to that preceding. Electrons photoelectrically emitted from the cathode are drawn to the first dynode; with a secondary emission ratio greater than unity, secondary electrons are emitted which, in turn, give rise to an amplified current from the next dynode. By the time the electron stream has reached the anode, the original photocurrent is amplified

[1] Secondary electron-emitting electrode.

δ^n-fold, *where δ is the secondary electron emission ratio of the dynode and n is the* number of dynodes.

The multiplier phototube has a number of advantages compared with a phototube and separate amplifier. Since the amplification is entirely that of a single primary stream of electrons, the incident light which actuates the current may be relatively constant or it may be chopped, as by means of a rotating shutter, and the gain remains constant. Of still greater advantage, especially for the measurement of light at low intensity, is the high signal-to-noise ratio obtained.

In considering the signal-to-noise ratio of the multiplier phototube, it should be noted that total absence of light does not result in zero anode current. The small current observed under such conditions is known as the "dark current," the principal components of which are (1) amplified thermionic emission, (2) leakage current, (3) regenerative ionization. At high levels of cathode illumination, the dark current is likely to be of minor importance; at low levels, such as in astronomical work, the dark current may be important, although the resultant "noise" is still low compared to what would be obtained in a unit containing a phototube and separate amplifier having the same gain and a band width equal to that of the equipment into which the multiplier phototube operates.

19. Secondary Emission. A third way in which electron emission may be produced is by the bombardment of a conducting or semiconducting solid with electrons or positive ions, known as *secondary emission.* Such an emitter, when used as an electrode of an electron tube, is called a *dynode.*

Secondary emission may be obtained by electron bombardment of pure metals, although the yield is not great. In this case a part of the energy of the bombarding or *primary electron* is transferred to one or several conduction electrons of the solid. If the surface-directed energies of the newly excited electrons are greater than the work function ϕe, the energy required for their exit, they may be emitted as *secondary* electrons. In the case of pure metals, the ratio of secondary electron current to primary electron current, δ, is not appreciably affected by temperature.

When the secondary-electron-emitting electrode or dynode is a composite surface properly prepared for use as such, δ may be made considerably greater than unity with the result that a weak electron current, such as that from a photocathode, may be amplified many times by secondary emission. Other uses of the phenomenon are found in the dynatron and in the orbital-beam tube. The secondary emission ratio of such dynodes is not entirely independent of temperature.

The mechanism of secondary emission from composite surfaces is generally considered to be different from that of pure metals. In the latter case the "free" electrons of the metal are thought to provide the secondary electron current. In the case of composite surfaces, certain compounds of the metals, especially those of the second and third columns of the periodic table, provide much higher values of δ than do the pure metals. Among the best compounds are barium oxide and magnesium oxide; sulfides, halides, etc., of these metals are not satisfactory. Here the secondary emission is provided by the excitation, due to the energy of the incident primary electron, of the electrons of the outermost shells of atoms constituting the emitting material. In such a case it is considered that the permitted energy bands for electrons in the compound are either entirely empty or completely filled, and that a bombarding primary electron can lose its energy by causing the transition of an electron from a filled band to an empty band. The chance that an excited electron shall leave the body depends upon the position of the empty band with respect to the occupied band *and* the potential outside the body.

If all the energy brought into the body by the bombarding primary could be transformed into the energy required for the emission of secondary electrons, the ratio δ would be very high. If V is the voltage between dynode and cathode, the energy of the primary just inside the dynode would be $Ve + \phi e$; the energy would be transformed to n secondary electrons having a total energy $n\phi e$. Thus the maximum number n that could be emitted would be $n = V/\phi + 1$. There are a number of reasons why this is not realized in the actual case:

1. The energies of the excited electrons are randomly distributed in direction; it is only the surface-directed component of the energy of an individual electron that determines whether it shall be emitted.

2. The majority of the emitted secondary electrons receive considerably more energy from the primaries than is required for emergence. Thus the average initial velocity of secondary electrons is greater than in the case of thermionic or photoelectric emission.

3. The energy of the primary electron, especially when the potential of the dynode with respect to the cathode is high, may not be expended until the primary electron has penetrated to a considerable distance below the surface of the dynode, in which case the chance that electrons excited by the primary shall be emitted is considerably reduced.
FIG. 5. When primary electron stream is directed normally to the surface of the dynode, the secondary emission ratio reaches a maximum value as the primary energy is increased. Curve is for magnesium oxide. (*After Bruining and de Boer.*)
FIG. 6. Secondary emission ratio at various angles of incidence of primary electrons. Curve is for nickel. (*After Bruining and de Boer.*)

Typical examples of the manner in which the depth of penetration of the primary electrons affects the magnitude of the secondary electron current are shown in Figs. 5 and 6, both of which were redrawn from the data of Bruining and de Boer.

In Fig. 5 the ratio δ of secondary to primary current for magnesium oxide–coated platinum dynode is seen to rise from zero at very low dynode voltage almost linearly at low voltage, then gradually reaches a maximum value at about 700 volts, after which δ falls to lower values as the voltage is further increased. The curve is taken as a demonstration of the contention that, when the energy of the primary electron is high, much of it is transferred to other electrons at a distance so far below the surface that the chance of a secondary electron being emitted is greatly reduced.

Figure 6 shows the manner in which δ varies with the angle of incidence of the primary beam when the magnitude of the primary current and the potential of the dynode are held constant. It is assumed that, as the angle between the beam and the surface of the dynode is reduced, the depth of penetration of the primary electrons is reduced; hence the average distance between the surface and the point at which the maximum excitation occurs is lowered. The result is an increase in the secondary electron current or δ.

In practice, dynodes are made by activating the surface of a base metal either by oxidation, by distillation onto it of a sensitizing material, or by heat-treatment to bring an impurity sensitizer to the surface.

An example of the first-named class of activation is that in which the base metal is

an alloy consisting largely of magnesium, such as Dowmetal. The dynode is cleaned by mechanical processes, then heated in an atmosphere of oxygen from which water vapor and nitrogen have been excluded to produce a thin film of magnesium oxide.

In sensitizing by the distillation of sensitizing materials onto a base, one of several processes may be used. Barium or magnesium, or a combination of both, may be volatilized onto a nickel base *in vacuo*, then oxidized by admitting a small amount of oxygen to the device and applying a spark coil so that a glow discharge is created.

A useful method comprises using a well-cleaned and outgassed silver or copper electrode upon which a film of cesium is deposited by vaporization from a side tube; the cesium is then oxidized by a glow discharge in low-pressure oxygen. After removal of the residual oxygen, a further small quantity of cesium is admitted. Dynodes made by this process have superior properties when properly prepared, the reason apparently being that the secondary electrons originate within the cesium oxide lattice where they are readily excited, while the metal cesium coating, because of its low work function, facilitates their escape.

For activation by means of an impurity material in the dynode, the dynode ordinarily consists of silver containing a few per cent by weight of magnesium. Activation consists in heating the dynode for a period of at least several minutes in the presence of oxygen, during which time some of the magnesium diffuses to the surface where it becomes oxidized.

In most cases where secondary emission is used, care is usually taken to ensure that the dynode is shielded from being contaminated by the cathode. While it is true that an electrode may be activated solely by contamination from an oxide-coated cathode, such activity is low compared to that produced by the methods just described and has relatively short life. A good dynode is, therefore, effectively spoiled by cathode contamination. The orbital-beam tube is an example of one way in which the dynode is protected.

Secondary emission often occurs as a spurious effect in various kinds of electron tubes, especially through transfer of activating material from the cathode to the anode or a grid. This is particularly noted in tubes employing oxide-coated cathodes. In the case of tetrodes the effect appears as a major shift in screen-grid current and in plate resistance during the life of the tube even with no change in cathode current. A fairly effective remedy for this condition is to spray the grid with carbon black or boron carbide and to carbonize the plate by first oxidizing the surface, then heating it in a carbon-bearing gas such as methane, CH_4. The real solution to the problem is, of course, the employment of a suppressor grid held at a low voltage such that the field on both sides of it suppresses the emission of secondary electrons.

Secondary emission plays an important part in the operation of television pickup tubes; it is beyond the scope of this book to describe such a highly specialized device in detail. Secondary emission is also important in cathode-ray tubes in that it constitutes the means whereby the electrons striking the screen are able to reach the terminal for the screen voltage supply.

20. Field Emission. From an engineering standpoint, field emission is of less interest in the radio electron tube than are thermionic, photoelectric, and secondary emission currents; hence the discussion will be confined to a few remarks.

The relations describing quantitatively the phenomena of thermionic and photoelectric emission assume zero field at the surface of the cathode. When the field is not zero, the effect is equivalent to a change in the net work function by an amount

$$\Delta\phi = -\sqrt{-eF} \tag{17}$$

where F is the field or potential gradient just outside the surface of the cathode. In practical units,

$$\Delta\phi = -3.8 \times 10^{-4} \sqrt{-F} \qquad \text{volts} \tag{18}$$

in which F is in volts per cm.

Field emission is of greater interest in gaseous discharge devices than in high-vacuum tubes, but the phenomenon is one which must be considered in any application where strong fields are encountered, as in transmitting and rectifier tubes.

21. Spurious Emission Currents. In many cases the operation of a tube may be adversely affected by unwanted emission currents, and special means must be taken to prevent or reduce them. A brief description of the most common practices will be given.[1]

Grid emission may occur by any of the means already mentioned, the most common being thermionic or primary emission, and secondary emission; photoelectric emission is encountered in some tubes where the grid current due to gas or leakage is low enough for the photoelectric effect to become a factor.

Primary grid emission is encountered in receiving tubes employing oxide-coated cathodes where the spacing between grid and cathode is low and the dissipation on the electrodes is high in relation to their area. This is particularly noted in the output tubes, especially those intended for use in a-c–d-c receivers.

In most of the commercial receiving tubes where coated cathodes are used and where, without special precautions, grid emission would be a factor, radiators are welded to the ends of the grid side rods to keep the grid cool. Attention is given to the thermal conductivity both of the laterals and of the side rods; pure metals are preferred for the former, while beryllium-hardened copper is frequently used for the latter. For tubes used in oscillator service, the control grid is sometimes gold-plated or sprayed with finely powdered boron carbide if the type of operation is sufficiently severe to warrant this added expense.

For tubes employing thoriated tungsten filaments, the means employed to hold the grid emission to a low value depend to some extent upon the anticipated maximum grid temperatures. Where the temperature is not excessive, the grid may be made of platinum or of a more refractory wire which is platinum-clad, since platinum has the ability to absorb any thorium deposited upon it. For extremely high temperatures, the grid may be coated with certain refractory oxides, provided they do not break down with evolution of oxygen and cause decarburization of the filament. Good results have been reported with the oxides of zirconium and beryllium on molybdenum grids.

The means employed for the reduction of primary grid emission are usually effective in the control of secondary emission. However, the latter effect may be encountered in tubes having grids that operate at relatively low temperatures, in which case they may be sprayed with substances having a low coefficient of secondary emission such as carbon black, graphite, or zirconium.

Tubes are frequently designed for use wherein the anode may, during part of a cycle, be at a potential lower than some other electrode, as in rectifiers and tetrodes; hence either primary or secondary emission from the anode may be a serious factor unless precautions are taken to prevent or limit its occurrence. Where the tube is a diode rectifier, emphasis is placed upon the radiating properties of the anode so that the temperature will be low enough to limit primary emission. For small tubes, the anodes are commonly made of carburized sheet nickel. In large tubes the anode is made with radiating fins and is sand-blasted and coated with zirconium, the latter serving both as a getter and in improving thermal radiation.

For tetrodes, the problem of thermionic emission from the anode is less frequently encountered. Secondary emission may be held at a minimum by the use of carburized metal, or by a zirconium spray on the inside of the anode. To a considerable extent, however, this problem is more of academic than of practical importance, since the use of a suppressor grid as used in pentodes is a more practical solution.

SPACE-CHARGE-LIMITED CURRENTS

22. Diodes. A space-charge-limited current in an electron tube is an electron current which depends only upon the configuration and potentials of the electrodes

[1] An excellent discussion of the effects of operating conditions on spurious currents and on changes in electron emission is given in "Techniques for Application of Electron Tubes in Military Equipment," Document PB111644, U.S. Department of Commerce, Office of Technical Services, Washington 25, D.C.; price $2.50.

and is *not* limited by the thermionic emission of the cathode. In this section all the relations are to be taken as being of practicable value only to the extent that adequate emission is available.

In a diode having a unipotential cathode, the current is given by the relation

$$i = Ge_p^{3/2} \tag{19}$$

in which G is the perveance and e_p the instantaneous anode voltage. In the formulas which follow, G will be expressed in terms of amperes per volt$^{3/2}$.

Where the cathode is a filament, the voltage drop E_f across the filament must be considered, and this requires modification of Eq. (19). Commonly the anode voltage is larger than the filament voltage, and return connections are made to the negative end of the filament. For this case the current is expressed as

$$i = \frac{2}{5}\frac{G}{E_f}\left[e_p^{5/2} - (e_p - E_f)^{5/2}\right] \tag{19a}$$

where G is now the perveance for a unipotential cathode tube of the same dimensions.

Where the value of e_p is several times that of E_f, it is ordinarily of sufficient accuracy to use the relation

$$i = G(e_p - E_f/2)^{3/2} \tag{19b}$$

for connection to the negative end of the filament. For connection to the center tap of a filament-heating transformer, E_f in Eq. (19*b*) is omitted in considering the d-c component of the current.

For *parallel-plane* electrodes,[1]

$$G = 2.34 \times 10^{-6} A/x^2 \tag{20}$$

where A = electrode area
x = electrode spacing

The physical dimensions may be taken in any units for Eq. (20) or the formulas to follow, since the units cancel out.

For *coaxial cylinders*,[1]

$$G = 14.65 \times 10^{-6} L/r\beta^2 \tag{21}$$

where L = length of electrodes
r = radius of anode
β^2 = a function of r/r_o shown graphically in Fig. 7, r_o being the cathode radius

For tube electrode configurations other than parallel planes and coaxial cylinders approximation solutions are employed in computing the perveance. These are based on the equivalent-capacitance rule, which states that the space-charge-limited current between a cylindrical cathode and an anode of arbitrary shape is approximately that which would be expected for the same cathode and a symmetrical anode of such dimensions that the electrostatic capacitances are equal. The current relations for most of the electrode arrangements used in tubes may be derived from one or another of the seven expressions for the capacitance given below. In all these cases the capacitance is to be equated to that for a pair of coaxial cylinders, the radius of the outer cylinder being r and that of the inner one r_o. The resulting expression is then solved for r, and this value is then used in Eq. (21).

[1] The perveance equations (20) and (21) do not include corrections for initial electron velocity and contact potential difference; consequently they are only approximations for small spacings and low voltages. For parallel planes, the distance s is to be reduced by s_{min}, the distance between cathode and plane of potential minimum or virtual cathode. Where $i_s \gg i$, it is sufficiently accurate in most cases to take this distance as $s_m = 2.7 \times 10^{-8} T^{3/4}/i^{1/2}$ cm, where T is the temperature of the cathode in deg K and i is the current density in amp per sq cm.

In the case of coaxial cylinders where r/r_o is not great, the correction in r_o is somewhat less than for planes and becomes vanishingly small for high values of r/r_o.
FIG. 7. Values of β^2 for r/r_o.

For coaxial cylinders, the capacitance is

$$C = \frac{l}{2 \ln (r/r_o)} \tag{22}$$

where l = length.

As an example of application, the rule will be applied to the case for a cylindrical anode surrounding a cylindrical cathode, the axes being separated a distance a. The capacitance for this electrode arrangement is

$$C = \frac{l}{2 \cosh^{-1} [(r_a^2 + r_o^2 - a^2)/2r_a r_o]} \tag{23}$$

where r_a = anode radius
r_o = cathode radius

When this expression is equated to Eq. (22), one has

$$\ln (r/r_o) = \cosh^{-1}\left(\frac{r_a^2 + r_o^2 - a^2}{2r_a r_o}\right) \tag{24}$$

To solve for the current, one simply takes

$$\frac{r}{r_o} = \frac{1}{2.3} \log_{10}^{-1}\left[\cosh^{-1}\left(\frac{r_a^2 + r_o^2 - a^2}{2r_a r_o}\right)\right]$$

to obtain r and r/r_o. This value of r is substituted in Eq. (21) along with the proper value of β^2 obtained from Fig. 7.

The expressions for the remaining six arrangements of practical importance are as follows.

Cylinder Parallel to a Single Plane:

$$C = \frac{l}{2 \cosh^{-1} (h/r_o)} \tag{25}$$

in which h is the distance from cathode axis to plane. It should be noted that, when $h \gg r_o$, the equivalent cylindrical anode has a radius $r = 2h$.

Cylinder Midway between Parallel Planes:

$$C = \frac{l}{2 \ln [(4h^2 - r_o^2/2)/\pi h r_o]} \tag{26}$$

where h = distance from cathode axis to one plane.

For the case in which $h \gg r_o$, the expression may be simplified and one has

$$r = \frac{1.27h}{r_o}$$

Two Cylindrical Cathodes in a Cylindrical Anode:

$$C = \frac{l}{n\left\{\left[\dfrac{r_a^2 - a^2}{(r_a^4/a^2) - r_o^2}\right]\left[\dfrac{r_a^4/a^2 - (r_o + a)^2}{r_o^2 + 2r_o a}\right]\right\}} \tag{27}$$

In this expression it is assumed that both cathodes are on a line with the cathode axis, the cathode axes being displaced a distance a from the anode axis, and that $r_a \gg (r_o + a)$. The length of the equivalent coaxial cylinders is taken as twice the length of the two-cathode structure.

Cylindrical Anode with n Cylindrical Cathodes:

$$C = \frac{nl}{2n \ln (r_a/a) + 2 \ln [(a/nr_o)(1 - a^2/r_o^2)]} \tag{28}$$

In applying the rule, Eq. (28) is to be equated to

$$C = \frac{nl}{2 \ln (r/r_o)}$$

Cylindrical Anode with Helical Cathode:

$$C = \frac{L}{(2L/l) \ln (r_a/a) + 2 \ln [(al/Lr_o)(1 - a^2/r_o^2)]} \tag{29}$$

where l = length of helix
L = total length of wire in helix
a = radius of helix
r_a = radius of anode
r_o = radius of filament wire
In applying the rule Eq. (29) is equated to

$$C = \frac{L}{2 \ln (r/r_o)}$$

Folded Filaments. In tubes using wire or small ribbon filaments folded as an M or a V and placed between rectangular grids or anodes, the capacitance is computed as though a single wire were used in a system whose length is the emitting length of the filament. Even with ribbon filaments, the spacing is usually large compared with the dimensions of the cathode so that the simple relation $r = 1.27h$ is satisfactory for use in predicting the current.

23. Contact Potentials and Other Internal Effects. Where e_p of Eq. (19) is of the order of 10 volts or more, this can be taken as the instantaneous voltage e_b applied at the terminals of the tube. At lower voltages, e_p must be taken to include certain internal effects, primarily the contact potential difference between the electrode surfaces and initial electron velocity. As the voltage becomes very low, the current departs from the three-halves law of Eq. (19) and is said to be limited by a retarding field; usually some current is still obtained even when the applied voltage is slightly negative.

The contact potential difference between the electrodes is taken as minus the difference in the work functions ϕ_k and ϕ_a of their surfaces. Thus if there is no potential difference applied between the two electrodes, the potential *just outside* the anode is $-\phi_a$ volts with respect to the inside of either electrode, and the potential *just outside* the cathode is $-\phi_k$. So far as the field is concerned, it is the same as though the anode is placed at a potential $-(\phi_a - \phi_k)$ volts with respect to the cathode.

The principal effect of the initial electron velocity is the existence of the so-called *virtual cathode* at some distance from the cathode, the potential of which is less than any other place between the electrodes. For parallel planes, the potential of the virtual cathode with respect to the outside of the cathode is given as

$$V_{\min} = (-T/11{,}600) \ln (i_s/i) \tag{30}$$

where T = temperature of cathode, degrees K
i = current to anode
i_s = temperature-limited emission

While the contact potential difference and the voltage $V_{\min}$ are not the only internal correction voltages, together they constitute the important ones from an engineering standpoint, their sum being denoted by the symbol ϵ. Thus Eq. (19) may be taken as

$$i = Ge_p^{3/2} = G(e_b + \epsilon)^{3/2} \simeq G[e_b - V_{\min} + (\phi_a - \phi_k)]^{3/2} \tag{31}$$

where e_b is the externally applied voltage and ϵ is the internal correction voltage, its value ordinarily being of the order of ½ volt for small tubes when well aged.

Figure 8 shows graphically the manner in which ϕ_k, ϕ_a, $V_{\min}$, and e_b combine to control the space-charge-limited current in a tube. Taking the potential inside the cathode as zero, the potential just outside the cathode will be $-\phi_k$ volts, depending upon the material of which it is made. When the cathode is at a temperature high enough to supply a space-charge-limited current with an applied voltage e_b,

the potential at all points is as shown by curve *a*. Owing to initial velocity, more electrons are emitted than reach the anode; their charge results in a depression in the curve at point x on curve *a*. The potential at point x is $V_{\min}$ with respect to the outside of the cathode, or $(-\phi_k + V_{\min})$ with respect to the inside of the cathode. Now the *inside* of the anode is at a potential e_b with respect to the *inside* of the cathode; therefore, the *outside* of the anode is at a potential $(e_b - \phi_a)$ with respect to the inside of the cathode. The potential difference represented by e_p is here taken as that between the outside of the anode and the virtual cathode; hence

$$e_p = (e_b - \phi_a) - (0 - \phi_k + V_{\min})$$

which is the term within the brackets of Eq. (31).

Line *b* of Fig. 8 shows the conditions existing when the cathode is cold; the potential minimum is zero; hence $V_{\min} = 0$ and $e_p = e_b + \phi_k - \phi_a$.

Curve *c* is for the case where the cathode is heated and $e_b = 0$; the potential difference between anode and cathode is $\phi_k - \phi_a$. Since i is now less than when $e_b > 0$, $V_{\min}$ (point x') is a greater negative voltage than before and is located much nearer to the anode.

FIG. 8. Effects of work functions and potential minimum on the field in a diode with parallel plane electrodes. Curve *a* is the potential distribution for a space-charge-limited current; curve *b*, potential distribution when emission is very low; curve *c*, potential distribution with cathode hot but with zero applied voltage.

The experimental value of ϵ may be determined to a useful degree of accuracy when the plate current and plate resistance are known. If it is assumed that the perveance G and potential minimum $V_{\min}$ in Eq. (31) are relatively constant with change in applied voltage e_b, the derivative de_b/di may be taken as the plate resistance r_p of the tube at the corresponding plate voltage. The result is solved for ϵ, giving

$$\epsilon = \tfrac{3}{2} i r_p - e_b \qquad \text{volts} \tag{32}$$

where i and r_p are expressed in amperes and ohms, respectively.

The importance of the correction voltage ϵ in connection with tubes containing grids will be shown in the discussion of the transconductance of triodes.

24. Triodes. In triodes the space-charge-limited cathode current is controlled in a manner analogous to that in the diode. In a triode, or a tube with more than one grid, the voltage of each electrode contributes to a composite controlling voltage of an equivalent diode anode, the dimensions of which are influenced by the dimensions of all of the actual electrodes except the cathode. The expression for cathode current is

$$i = G(e')^{3/2} \tag{33}$$

where G is the perveance of a diode having the same cathode and an anode of the same dimensions as the equivalent diode anode. The voltage e' is the composite controlling voltage.

For a triode having a high amplification factor, the equivalent diode anode may be taken as coinciding with the grid. Where such an assumption is not warranted, the following relations for locating the equivalent diode anode are generally of sufficient accuracy for design purposes.

1. *Plane electrodes:*

$$x' = (\mu x_1 + x_2)/(\mu + 1) \tag{34}$$

where x' = distance between cathode and equivalent diode-anode
x_1 = distance between cathode and grid plane measured to center of grid wire
x_2 = distance between grid plane and plate
μ = amplification factor[1]

Where the cathode is a plane parallel to the grid, the perveance is that given by Eq. (20) when x' is substituted for x. Where the grid and plate are parallel planes and the cathode is a wire, x' is taken as the distance h between the cathode axis and a parallel plane diode-anode. The reader is reminded that in computing the current, Eq. (21) may be used by substituting $2r$ for h as was discussed in connection with Eq. (26).

As a singular case, the equivalent diode-anode of a triode in which all three electrodes are parallel planes is located almost precisely in the plane of the grid if the composite controlling electrode voltage is expressed in the form

$$e' = \frac{\mu e_c + e_b}{\mu + 1 + \frac{4}{3}(x_2/x_1)} + \epsilon \tag{35}$$

2. *Cylindrical electrodes:* the radius r' of the equivalent diode-anode is given with reasonable accuracy by

$$r' = \log^{-1} [(\mu \log \rho_p + \log \rho_g)/(\mu + 1)] \tag{36}$$

where ρ_g and ρ_p are, respectively, the radii of the grid (to center of grid wire) and of the plate. The value of r' given by Eq. (36) is used directly in Eq. (21) for perveance.

3. Where the grids are *oval* and the plate is either oval or circular in cross section, certain approximation methods are useful. The distance between the equivalent diode-anode and cathode axis is taken in the vertical plane where the grid-cathode spacing is minimum, and computed as for plane electrodes.

Since the average spacing is greater than the minimum, an experimentally determined correction factor must be employed; usually it is about 0.7. A somewhat more accurate method is to divide the cross section of the tube into sectors and compute each sector separately. The current is then the sum of the currents in each sector, the mutual conductance is the sum of the mutual conductances of each sector, and the amplification factor is given by solving Eq. (47).

The composite controlling electrode voltage e' for triodes, except where Eq. (35) applies, is given by the relation

$$e' = \frac{\mu e_g + e_p}{\mu + 1} \tag{37}$$

where e_g and e_p are the grid and plate voltages, respectively. Where e' is of the order of 10 volts or more, it is generally satisfactory to take the electrode voltages applied to the tube terminals, *i.e.*, $e_g = e_c$, $e_p = e_b$, where e_c and e_b are, respectively, the applied grid and plate voltages.

Where e' is low, as in receiving tubes having a high amplification factor, e_g and e_p of Eq. (37) must be taken to mean that correction voltages are included. Although the contact potentials of grid and plate are usually not identical, it is convenient to disregard this fact, the error in so doing being negligibly small. In this case the composite controlling voltage may be written in terms of the applied voltage and a single correction voltage in the form

$$e' = \frac{\mu e_c + e_b}{\mu + 1} + \epsilon \tag{38}$$

25. Evaluation of Correction Factor ϵ. As will be shown later, the value of ϵ is a factor in the determination of the characteristics of the tube: hence means are required

[1] For design purposes, the amplification factor used is the mu factor (μ_{pgk}), meaning the magnitude of the quotient of plate voltage change by grid voltage change for constant cathode current.

for its evaluation. For purposes of design, it is computed from static and dynamic readings. For purposes of quality control an approximate value is obtained by a simple measurement. Both methods are described below.

1. For design applications, the value of ϵ is readily found from a set of bridge readings made under the conditions for which ϵ is to be determined. In a triode, the cathode current is the same as in a diode when the equivalent diode-controlling voltage e' as given by Eq. (37) is substituted for e_p in Eq. (19). The expression becomes

$$i = G\left[\frac{\mu e_c + e_b}{\mu + 1}\right]^{3/2} \tag{39}$$

Now if the grid is negatively biased, the current i is the plate current i_b and the transconductance g_m is the rate of change in plate current with change in grid voltage, plate voltage held constant. Assuming the perveance G in Eq. (39) to be constant with change in grid voltage, the derivative di/de_c is taken and G eliminated. This results in the useful relation

$$\epsilon = \frac{3i\mu}{2g_m(\mu + 1)} - \frac{\mu e_c + e_b}{\mu + 1} \quad \text{volts} \tag{40}$$

Thus the measured values of plate current, amplification factor, and transconductance at the voltage conditions of measurement may be set into Eq. (40) to obtain ϵ. The value so obtained is in most cases slightly too high because G was taken to be constant, but the error usually cancels out when such values of ϵ are put back into a design equation where the same assumption is allowed. Attention is called to the fact that, if the current i is expressed in milliamperes, g_m is to be expressed in millimhos.

Fig. 9. Circuit for rapid check of grid internal correction voltage. A microammeter may be placed in the grid circuit for checking both positive and negative values by the slower method.

In most cases where ϵ is of importance, *i.e.*, in high-gain receiving tubes, its value is likely to be between +0.3 and +1.0 volt. Where a value in excess of 1 volt is noted, the tube may be poorly aged. In tubes having gold-plated control grids, as in some computer types, the correction voltage is sometimes negative. For amplifier tubes used in "hybrid" autosets, ϵ is of special importance because the available battery voltage is so low. Further comments on the correction voltage will be found in the paragraphs dealing with transconductance and converter tubes.

2. While Eq. (40) gives the value of ϵ with accuracy necessary for purposes of design or redesign, test results satisfactory for quality-control purposes may be obtained using the circuit shown in Fig. 9. The resistor R ordinarily has a value of 10 megohms, and the plate supply is adjusted to a value that results in a plate current of approximately rated value for the average tube when the grid return is through resistor R (switch in position b). The cathode is heated at rated operating voltage, and the plate current is carefully noted. The switch is then thrown to position a and the plate current returned to its original value by adjustment of the potentiometer. The voltmeter then reads the internal correction voltage ϵ, sometimes incorrectly referred to as the "contact potential." It should be noted that for directly heated cathodes the test should be made with direct current only and with the grid return made to the negative end of the filament.

The correction voltage is usually positive, but tubes are occasionally found in

which the correction voltage is of negative polarity. Where knowledge of the magnitude of such a voltage is required, a microammeter may be placed in the grid circuit and the voltmeter reversed so that a positive voltage is applied to the grid. The voltage at which grid current just begins to flow is then noted. In either case, the correction voltage is minus the voltage being applied by the potentiometer.

26. Mu Factors. In general, the mu factor μ_{jlm} of an electron tube is the magnitude of the quotient of the alternating voltage of electrode j by the alternating voltage of electrode l under the condition that the current to electrode m remain constant. In amplifier circuits, the amplification factor μ_{pgp} is of most general interest, although, as has been noted, μ_{pgk} is used in tube design, since it is the total cathode current that is directly related to the composite controlling voltage.

In certain cases of restricted interest the mu factor μ_{gpg} of a triode with positive grid and negative plate is taken, the value of the factor being less than unity. It should be pointed out that in such operation the perveance G is considerably reduced by electrons that pass twice through the grid, the reason being that an electron moving in the grid-to-cathode direction has the same effect upon the space charge as an electron moving in the usual direction.

In the paragraphs immediately following, it is assumed that $\mu = \mu_{pgk}$ or, of course, μ can be μ_{pgp} if it is assumed that the grid draws no current from the electron stream and that the frequency is low.

Several formulas have been published for μ in terms of the dimensions of the tube. Those of Vogdes and Elder are commonly used and are given below. The distance between grid and cathode and the shape of the cathode are not factors, although they do have some influence when the spacing or the composite controlling electrode voltage is low.

For parallel-plane electrodes,

$$\mu = k_1 x_2 - k_2 \qquad (41)$$

For coaxial cylinders,

$$\mu = k_1 \rho_g \ln (\rho_p/\rho_g) - k_2 \qquad (42)$$

where x_2 = grid-plate spacing for parallel electrodes
ρ_g = radius of grid
ρ_p = radius of plate
$k_1 = 2\pi n/\ln \coth 2\pi nr$
n = grid turns per unit length
r = radius of grid wire
$k_2 = (\ln \cosh 2\pi nr)/(\ln \coth 2\pi nr)$

It is seen that, for plane electrodes, μ varies directly as the grid-plate spacing. For cylindrical electrodes, differentiation of μ with respect to ρ_g shows that μ is maximum when $\rho_g = \rho_p/2.718$, which means that, for this ratio, accidental variations in ρ_g or ρ_p result in minimum variation in μ.

Values of k_2 are seen not to vary with x_2, ρ_g, or ρ_p and are small in magnitude; hence they are frequently ignored in adjusting the dimensions of a tube to achieve an alteration in μ. Figure 10 provides a convenient means for the evaluation of k_1 in terms of wire size in inches and winding in turns per inch.

It is often necessary to design triodes in such a manner that the distance between the grid and anode is varied circumferentially, *e.g.*, where the grid is oval and the anode either cylindrical or rectangular in cross section. It is evident that the density of the electron stream is likely to be greatest where the grid-plate spacing is smallest, and so that part of the structure will largely determine the amplification factor. For such a tube, a preliminary design is tested in which the minimum distance is taken as x' in Eq. (34); final adjustment will be based upon an effective value of x' determined by measurement of μ for the preliminary samples.

27. Mu-slop and Cutoff. When the anode current is reduced by either decrease in anode voltage or increase in negative grid voltage, μ is observed to decrease. This decrease is generally not great where the effective controlling electrode voltage is of

the order of several volts, but as the current is decreased to the order of some microamperes the decrease in μ becomes pronounced. This effect, known as mu-slop, is due to a number of causes. Slight variations in dimensions, such as the misplacement of a grid wire or incomplete coverage of the plate by the grid, may permit the passage of current through one part of the tube when it has been cut off at all other parts. The effect is that the μ of the tube is, under this condition, the same as though the entire tube were made with a more open-spaced grid.

Mu-slop plays an important part in the determination of cutoff, although the extent is not always easy to determine. Reference to Eq. (39) indicates that the current is zero when the bracketed term is zero. However, as the term approaches zero, μ decreases and ϵ increases,[1] neither change being readily predictable. Mu-slop is most pronounced in receiving tubes having indirectly heated cathodes while the change in ϵ is greatest for tubes having high emission. Furthermore, the mu-slop at a given value of plate current increases as the plate voltage is increased. In view of these uncertainties, it is not possible to predict the precise value of grid voltage at which the current shall be some arbitrary low value. However, the following empirical relation is used in setting up a quality test for cutoff voltage for a current maximum of 10 μa:

$$e_{co} \cong -1.35 e_b/\mu \tag{43}$$

where e_{co} is the grid voltage applied and e_b and μ are the rated values. For pentodes, e_b is replaced by e_{c2} and μ by the triode mu, μ_1.

28. Transconductance and Plate Resistance. Differentiation of Eq. (39) also provides the relation which gives the grid-plate transconductance or mutual conductance g_m in terms of amplification factor, plate current, and electrode voltages. Equation (39) is to be taken with e_c sufficiently negative so that all of the current goes to the plate. The result may be expressed in the form

$$g_m = \left(\frac{di_p}{de_c}\right)_{e_c} = \frac{3}{2} G \left(\frac{\mu}{\mu + 1}\right) \left(\frac{\mu e_c + e_b}{\mu + 1} + \epsilon\right)^{1/2} \tag{44}$$

where i_p is the plate current, the grid current being zero. Equation (44), with elimination of G by means of Eq. (39), gives the useful relation

$$g_m = \frac{3}{2} \frac{\mu i_p}{\mu e_c + e_b + \epsilon(\mu + 1)} \tag{45}$$

from which Eq. (40) was taken by rearrangement of the terms. Note that if i_p is expressed in milliamperes, g_m is in millimhos.

In the discussion of diodes it was indicated that the perveance formulas do not hold when the anode-cathode distance becomes very small. This is also true in tubes having grids, so that Eqs. (44) and (45) also fall down under such conditions. The maximum theoretical value of g_m is of the order of 10^4 μmhos per ma.

Expressions for the plate resistance r_p may be derived just as Eqs. (44) and (45) were obtained by taking $1/r_p = (di_p/de_b)$, the result being merely a demonstration of the well-known rule that

$$r_p = \mu/g_m \tag{46}$$

A relation that is very useful in tube design is obtained from Eq. (45) for determining the amplification factor necessary when the values of g_m, i_b, e_c, and e_b are specified, which constitutes one of the first steps necessary in the design of any tube having one or more grids. The equation is

$$\mu = \frac{2g_m(e_b + \epsilon)}{3i_b - 2g_m(e_c + \epsilon)} \tag{47}$$

[1] The potential minimum, an important part of ϵ, is seen in Eq. (30) to vary as i varies; as i decreases, V_{min} increases negatively while the contact potential difference, $-(\phi_a - \phi_k)$, presumably remains constant; thus ϵ changes in the positive direction.
FIG. 10. Evaluation of k_1 in terms of wire size in inches and winding in grid turns per inch.
FIG. 10. (*Continued*)

Inspection of Eq. (47) shows that, for required values of g_m, i_b, e_c, and e_b, a high value of ϵ requires a higher value of μ than would be required when ϵ is low. It is, therefore, important to know at the start, especially in a high-mu triode or a high-gain, sharp cutoff pentode, how low a value of ϵ may be expected from the tube when well aged or what its value will be after some hours of operation.

Control of ϵ. As previously noted, the expected value of ϵ cannot be predicted with accuracy, but reasonable estimates of the probable value can be based on similar tubes. Variations from average for a type, whether the variation is among individual tubes or changes during life, are important considerations in the control of quality of high-gain tubes.

Equation (40) assumes full space-charge-limited current, but when the current of a tube is partially temperature-limited, the quotient of plate current by transconductance is high; hence such a tube may be expected to show a very high value of ϵ when so computed. For this reason, tubes which apparently have an internal correction voltage much above 1 volt should be checked for emission.

Apart from the effect of poor or unstable emission, the principal cause of variation in ϵ is usually the variation in contact potential of the control grid. In tubes having coated cathodes this variation may be as much as 1 volt; in tungsten-filament tubes it is usually small. Where a coated cathode is used, the grids appear to become contaminated by the cathode during life so that the actual contact potential difference approaches a very low value; hence ϵ approaches the value of $-V_{\min}$. In most indirectly heated tubes, ϵ will become stable after the tube has been in use for 50 or 100 hr. In high-mu triodes and in high-gain receiving-type pentodes with coated cathodes the grid contact potential may be partially stabilized by taking tubes initially at room temperature and raising the heater voltage fairly rapidly to about twice the rated value and holding the condition for about 30 sec, then turning off the current. No other voltages are applied and the cathode must not be heated longer than indicated, since otherwise the grid becomes heated and the condition is reversed. The process may be repeated a number of times, usually with some continued change in ϵ, provided sufficient time is allowed between treatments for the grid to cool off. The treatment is the same regardless of whether ϵ is originally higher or lower than the stable value finally obtained.

In tubes having coated cathodes made for industrial purposes, where constant characteristics over a period of some thousands of hours is a primary requisite, special means are employed for maintaining the contact potential at its initial value. The cathodes are frequently designed so that the temperature is somewhat lower than that of similar radio receiving tubes. This reduces the rate at which coating is volatilized; hence the maintenance of the coated diameter and activity of the cathode is improved and the rate of grid contamination is reduced.

29. Division of Current in Positive-grid Triode. The manner in which the total cathode current of a positively biased tube divides between grid and anode cannot be specified with any high degree of accuracy. There are, however, formulas that yield fair results in the absence of grid primary or secondary emission and are based on the following concepts:

1. When the grid is at its "natural" potential, the ratio of grid current to plate current is the quotient of grid wire diameter by the distance between grid wires.

2. The ratio of plate current to grid current varies approximately as the square root of the ratio of plate voltage to grid voltage.

The term *natural potential* means the voltage E_γ which, applied to the grid when the plate is at the arbitrary voltage E_π, results in the same cathode current as would have been obtained with the grid physically removed. If the *cathode, grid, and plate are all planes,*

$$E_\gamma = E_\pi \left(\frac{x_1}{x_1 + x_2} \right)^{4/3} \tag{48}$$

where x_1 and x_2 are, respectively, the cathode-grid and grid-plate spacing.

When cathode, grid, and plate are all coaxial cylinders, the natural potential of the grid is

$$E_\gamma = \left(\frac{\rho_g \beta_g{}^2}{\rho_p \beta_p{}^2} \right)^{2/3} E_\pi \tag{49}$$

where ρ_g and ρ_p are, respectively, the grid and plate radii and β_g^2 and β_p^2 are obtained from Fig. 7 using ρ_g/r_0 and ρ_p/r_0, respectively, r_0 being the cathode radius.

For these two cases, one may then take as an approximation, in the absence of primary or secondary emission from the grid, the empirical relation:

$$\frac{i_b}{i_c} \simeq \left(\frac{s - d}{d}\right) \left(\frac{e_b E_\gamma}{e_c E_\pi}\right)^{1/2} \tag{50}$$

where i_b and i_c = plate and grid currents
e_b and e_c = plate and grid voltages
s = spacing between grid wires on centers
d = grid wire diameter

For the case in which the cathode is a wire or ribbon, grid and plate are planes, Spangenberg gives the relation:

$$\frac{i_b}{i_c} = \frac{L + M(E_b/E_c)}{P - Q(E_b/E_c)} \tag{51}$$

where $L = \pi s p \mu - s\mu(p + f)D - 2\pi p r_g \mu$
$M = \pi s p - 2\pi p r_g + sfD\mu$
$P = s(p + f)\mu + 2\pi p r_g \mu$
$Q = sfD\mu - 2\pi p r_g$
s = spacing between grid wires
r = grid wire radius
p = grid-plate spacing
f = filament-grid spacing
μ = amplification factor of tube
$D = r_g/2f \ln (4ef/r_g)$, where $e = 2.718$

30. Tetrodes. Tubes having two grids between cathode and anode are the more common types of tetrodes. The grid nearest the cathode, designated g_1, is ordinarily operated with negative bias and the second grid, g_2, is used to provide increased gain or power output and reduced control grid-plate capacitance. Such tubes suffer by comparison with pentodes in their performance, owing largely to the fact that secondary emission reduces the plate resistance r_p, therefore the gain; the secondary emission varies with life, causing a shift in tube characteristics. In addition, the feedback capacitance is lower in a pentode, thus permitting full advantage of the higher r_p.

The perveance G and internal correction voltage ϵ of a tetrode may be computed or measured provided the conditions are such that electrons are not made to reverse their directions and affect the space charge in the region of the cathode. Under ordinary conditions a small change in plate voltage produces a relatively insignificant change in cathode current. The change in plate current with small change in plate voltage is usually found to be accompanied by a change in screen-grid current which is opposite in direction and almost equal in magnitude, while the change in cathode current is very small indeed. Hence the perveance is practically the same as if the screen grid were replaced by an anode, the potential of this anode being that of the tetrode screen grid. Under these conditions,

$$i = i_b + i_{c2} = G\left(\frac{\mu_1 e_{c1} + e_{c2}}{\mu_1 + 1} + \epsilon\right)^{3/2} \tag{52}$$

where μ_1 = triode amplification factor
i_b = plate current of tetrode
i_{c2} = screen-grid current
e_{c1} = control-grid voltage
e_{c2} = screen-grid voltage

The value of G is then related to dimensions as in the case of a triode. For determining the perveance and the internal correction voltage of an experimental tube from bridge

measurements, the screen grid and plate are connected at the socket and the normal screen-grid voltage is applied. The readings are then substituted in Eq. (52), $(i_b + i_{c2})$ now being the total triode plate current. Similarly, ϵ is obtained when the same data are placed in Eq. (40), the value of g_m now being that obtained for the triode connection and e_b being the voltage applied to the screen grid and plate tied together.

The transconductance of the tetrode is related to that of the triode as in Eq. (53) below, assuming that there will be zero change in the proportional division of current between screen grid and plate when a signal is applied to the control grid, and that the cathode current is the same for either triode or tetrode connection.

$$g_{m(\text{tetrode})} = (i_b/i_k) = g_{m(\text{triode})} \tag{53}$$

where i_b = tetrode plate current
i_k = total cathode current $(i_b + i_{c2})$

The relation $g_m = \mu/r_p$ holds for a tetrode as for any other tube. However, the values of μ and r_p are not readily predictable from the dimensions in view of the fact that the ratio of screen current to plate current changes when a signal is applied to the plate. This change acts to reduce r_p and μ. If the change were zero, the tetrode amplification factor would be approximately equal to the sum and product of (1) the mu of the tube as a triode with the screen grid omitted and (2) the mu of the tube as a triode if the screen grid were the only grid in it. To keep the amplification factor as high as possible, the distance between screen grid and plate is made relatively large and the screen grid may be treated to hold the secondary emission low, as by spraying it with graphite. In transmitting tubes the wires of the screen grid are sometimes placed directly behind the wires of the control grid, thus achieving an increase in plate resistance and reduction in screen-grid dissipation.

31. Pentodes. A pentode is an electron tube having five electrodes: usually a cathode, an anode, and three grids. This discussion will be limited to the case where the electrons from the cathode pass successively through all three grids to the anode. In practically all cases the pentode may be considered as a tetrode in which a third grid is added between screen grid and plate for the purpose of suppressing secondary emission; hence the third grid is often called a "suppressor" grid. The principal results of suppressing secondary electrons are an increase in the amplification factor (hence an increase in gain), increase in power output, and decrease in distortion for large-signal tubes.

The manner in which the third grid suppresses the flow of secondary electrons is readily understood. With the suppressor at zero potential while both screen grid and plate are positive, the field toward the suppressor is retarding for electrons on both sides. Since the average initial velocity of most of the secondary electrons is equivalent to only a few electron volts, the energy is generally too low to allow them to pass through the suppressor. To a certain extent, the control of the secondary electrons is analogous to cutoff in a triode. For example, if μ_{3p} is the suppressor grid-plate mu, one could expect the flow of secondary electrons from the screen grid to the plate to be blocked when $(e_b - e_{c2}) + \mu_{3p}(-e_{c2}) = 0$. In the practical case μ_{3p} is made considerably greater, a minimum figure being

$$\mu_{3p} = 2(e_b - e_{c2})/e_{c2} \tag{54}$$

in which e_b is to be taken as the highest value of plate voltage likely to be encountered under full-signal operation. For ordinary receiving-type pentodes, μ_{3p} is about 15 to 20 when measured at $e_{c2} = 100$, $e_b = 250$, $e_c = 0$.

Figure 11 shows a typical curve of the electrode currents in a pentode plotted against suppressor voltage. Although the effect of the suppressor-grid voltage on the anode current is usually of no importance in ordinary amplifier operation, it is of interest in certain circuits such as multivibrators and square-wave generators. It is noted that the i_b-e_{c3} curve has a flection point at which the suppressor grid-plate transconductance is maximum. This corresponds approximately to the conditions under which half of

the electrons moving toward the plate are turned back by the suppressor grid. Under conditions approaching perfect symmetry, including alignment of the control and screen grids and a high value of μ_{3p}, the i_b-e_{c3} curve becomes very steep at the inflection point—which will occur with a very small negative bias on the suppressor grid—and the suppressor grid-plate transconductance approaches a theoretical maximum value which is of the order of 10,000 μmhos per ma plate current.

In Fig. 11 the cathode current has been plotted against suppressor-grid voltage. It is seen that, where the plate current increases rapidly with decrease in suppressor
FIG. 11. Variation in i_b, i_{c2}, i_k, μ_{3-p}, and r_p with variation of suppressor-grid voltage.

bias, the total cathode current also rises. This may be interpreted as showing the manner in which the cathode current is limited by electrons returned toward it from beyond the control grid, or, this being granted, as showing that some of the electrons repelled by a bias on the suppressor grid may again pass through both screen and control grids. Figure 11 was taken from a tube having substantially cylindrical electrodes. Had the filament been a wire and the other electrodes flat, the effect of the suppressor-grid bias on the cathode current would have been less noticeable.

The perveance of a pentode is taken in the same manner as in the case of a tetrode, the suppressor—where it has an external connection—being connected to the cathode. The equivalent diode-anode is then just beyond the control grid as in the triode, so that the data given in the discussion of diodes and triodes will apply here.

Similarly, the equivalent controlling electrode voltage may be taken by considering the screen grid to be equivalent to a triode plate; hence,

$$e' \simeq \frac{\mu_{12}e_{c1} + e_{c2}}{\mu_{12} + 1} + \epsilon \qquad (55)$$

32. Pentode Design. While it is beyond the scope of a handbook to outline in detail the design of a pentode, mention will be made of a few points which may aid in an understanding of the more difficult steps. It is assumed that the objective is a tube having specified values of i_b, i_{c2}, and g_m at specified values of e_{c1}, e_{c2}, and e_b.

1. The first step is to decide on a value of the internal correction voltage. If the tube is to resemble an existing tube to the extent that the values of ϵ could be expected to be alike, the existing tubes can be read as triodes and ϵ computed from Eq. (40). In the absence of such data, ϵ can be taken arbitrarily as, say, 0.7 volt in the preliminary test.

2. The required triode mu is computed from Eq. (47), using e_{c2} in place of e_b and e_{c1} in place of e_c. (Note that the screen current does not enter the relation, since the pentode g_m and i_b are the same fractions of the triode g_m and i_b, respectively.)

3. Assuming that the general configuration of the electrodes and the dimensions of the cathode have been picked, the dimensions of the composite anode are chosen to give the proper perveance as described in the paragraphs on diodes. The value of the perveance required will be

$$G = \frac{i_b + i_{c2}}{\left(\dfrac{\mu_{12}e_{c1} + e_{c2}}{\mu_{12} + 1} + \epsilon\right)^{3/2}} \tag{56}$$

where μ_{12} is the required triode amplification factor as computed by the method outlined in the preceding paragraph.

4. The surface dimensions of the control grid are first taken as being those of the composite anode, and the surface dimensions of the screen grid then chosen to have reasonable clearance and shape. The exact surface dimensions of the control grid may then be determined as for a triode. See Eqs. (34), (36), (41), (42), and accompanying text. When these results are at hand, good judgment will frequently indicate that a change may be necessary in some of the parts arbitrarily chosen; *e.g.*, a larger cathode might better be used, or a screen grid of smaller diameter might have some advantage. In the former case, a new composite anode must be computed; in the latter case, a new control grid will be computed for the smaller screen grid.

5. No attempt is made in the first design to produce a specified screen-grid current. The first batch of tubes must, in any case, be regarded as means to provide a basis on which to make corrections, and such corrections may include the correction for screen-grid current. In a shadow-grid (grid turns aligned) type of tube, the screen-grid current changes in the same direction as the diameter of the wire with which it is wound and, other factors being the same, increases as the distance between g_1 and g_2 is increased.

6. The dimensions of the plate are not especially critical so far as the design is concerned, but this is not to be taken as meaning that plates for a given design can be allowed to vary over wide limits. The plate is to be shorter than the grids to prevent the field at the ends from extending around the grids and influencing the electron current or resulting in unnecessarily high control grid–plate capacitance.

7. In view of Eq. (54) the mu of suppressor to plate must be adequate. On the other hand, μ_{3p} must not be too high for the reason that the plate resistance of the tube may be too low, especially when operating under the condition that $e_{c2} \simeq e_b$. The reason for this effect is discovered when it is considered that electrons, in passing close to the screen-grid wires, may have their paths bent in such a way that, while their total momentum is unchanged, the component in the direction of the retarding field of the suppressor is reduced to the point where a slight difference in plate voltage will have a major effect upon the probability that such an electron shall reach the plate. The writer knows of no formula that accurately predicts the dimensions of the ideal suppressor grid. When the suppressor grid has an external connection, some check may be obtained by measuring the plate resistance r_p of the tube with the potential of the suppressor changed a few volts above and below zero; if maximum r_p is

obtained with the suppressor negative, it is generally an indication that it would be advantageous to wind it with a tighter pitch; if r_p is maximum with the suppressor positive, the pitch may be opened. In any event, the final pitch selected is the result of comparative tests.

33. Shielding. In a pentode intended for r-f operation, shielding is used primarily for the reduction of control grid–plate capacitance. The design of shielding elements in a tube cannot be said to be based on formula. The evolution of shielding since the appearance of the first shielded tetrodes about 1925 might be considered as an example of intelligent cut-and-try engineering, particularly as exemplified in some of the high-perveance, single-ended pentode receiving tubes. In constructing experimental tubes the engineer who does not have available the advice of persons having experience in this phase of tube design will probably obtain best results if control grid and plate leads are taken out at opposite ends of the tube and the design features of commercial tubes, so far as shielding is concerned, are carefully copied. In such cases, the shields of discarded tubes are often found to be worth salvaging for experimentation.

34. Remote-cutoff Tubes. Ordinarily, remote-cutoff tubes are designed to fit a preferred curve of control-grid voltage plotted against either transconductance g_m or conversion transconductance g_c.

The control grid may be wound with a continuously variable pitch, the most open part being in the center. It is more practicable, however, in pentode amplifiers to use only three pitches—the most open being in the middle, then one or a few turns of an intermediate pitch each side of center, and a constant, close pitch over the balance of the length of the grid.

So far as the pentode is concerned, an approach to the problem of design is made by considering that the tube has three parts: one part having a high value of triode mu, one part having an intermediate value, and a third part having a low value. The length of each part of the tube is the same as that of the corresponding parts of the control grid. In the five paragraphs immediately following, the problem is considerably oversimplified, although it does show in outline a means for setting up a preliminary test. Final design is achieved, as with other tubes, by adjustment of factors that may be computed by measurement of the preliminary samples.

For the pentode amplifier, suppose three points on the g_m-e_{c1} curve are fixed at the bogey values that the design is expected to achieve. Let $g_{m(1)}$ be the mutual conductance at the low-bias end of the curve, the control-grid voltage being $e_{c(1)}$; at an intermediate point the values are $g_{m(2)}$ and $e_{c(2)}$ while at a point near cutoff they are $g_{m(3)}$ and $e_{c(3)}$. Correspondingly, there will be three values of plate current: $i_{(1)}$, $i_{(2)}$, and $i_{(3)}$.

At grid bias $e_{c(3)}$, the tube will be cut off all except at the one turn in the center. Here the triode mu, $g_{m(3)}$ and $i_{(3)}$, and the voltages will be related as in an ordinary triode or pentode, and the pitch of the control grid, n turns per unit length, is computed. The length of this part of the tube is $1/n$, and its current and transconductance for this section may then be computed to a reasonable degree of accuracy at any other value of grid bias.

At the intermediate point the current and transconductance of the low-mu section are computed and subtracted from the required values. The difference between this and $i_{(2)}$ and $g_{m(2)}$ is then made up by computing the length and mu of the intermediate section to give a total current and transconductance of the proper value for this point.

Similarly, at the low-bias end, the current and transconductance of the low and intermediate sections are computed and subtracted from the required values $i_{(1)}$ and $g_{m(1)}$. The difference is then taken and the high-mu section computed to bring the totals to the required values.

Such a procedure will often result, on first trial, in a computed cathode length which is not satisfactory as a practical design. The perveance per unit length may then be raised or lowered, as by altering the surface dimensions of the control grid, and a new set of computations made.

35. Beam-power Tubes. Also classed as pentodes are the so-called beam-power output tubes employing a cathode, anode, two grids, and a pair of beam-confining

plates, the latter taking the place of the suppressor grid in the high-gain pentode. The word *beam* is used to indicate that the wires of g_1 are interposed between the cathode and the wires of g_2 so that the electron stream is in the form of beams passing toward the anode. Figure 12 shows in cross section the electrode arrangement of a typical tube of this variety.

In a beam-power output tube the beam-confining plates are ordinarily connected internally to the cathode. While the relations between voltage, current, and mutual conductance and the dimensions of cathode, g_1, and g_2 are as in any other tube, the design from g_2 outward is still largely a matter of cut and try. Achievement of a satisfactory design is not difficult when the problem is understood in a qualitative way.
FIG. 12. Cross section of beam-power tube for low-voltage operation. Proper spacing between edges of beam-confining plates is important to performance.

Under full-signal conditions the instantaneous plate voltage of the tube will reach a value much higher than that of the screen grid, and to prevent secondary electrons from g_2 reaching the plate, a retarding field must be provided. Reference to Fig. 12 readily discloses that the retarding field due to the beam-confining plates would be minimum midway between the edges, increasing toward the edges. Therefore, to have sufficient field midway between the edges of the beam plates and not too strong a field toward the edge of the electron beam, the clearance between g_2 and anode should be relatively large and the beam-confining plates placed about halfway between.

When the plate voltage swings to its minimum value, the field between screen grid and plate must also be retarding to prevent the passage of electrons from the plate back to the grid. This adds up to an indicated requirement that the beam-confining plates have a fairly generous clearance on both sides. It will be understood that when a tube is delivering power to a load, the plate current is maximum when the plate voltage is minimum, and that the electrons passing between the edges of the beam-confining plates, because of their negative charge, further reduce the potential in the retarding region to a value that is considerably less than that under a charge-free condition. Now if the edges of the beam-confining plates are too close to each other, the beam is too closely confined and the charge density may become so great that many electrons are turned back toward the screen. The result of such a condition is low power efficiency and high distortion.

In practice, the design of the beam-confining plates is ordinarily settled by making samples with varying spacing between the edges. The tubes are tested for power output and distortion so that, with proper choice of load and a signal whose peak is equal to 95 per cent of the grid-bias voltage, tubes giving best power-output efficiency and lowest distortion are taken as the prototypes. In most cases a power-output efficiency $(100P_0/i_be_b)$ of 50 per cent can be obtained with a total (rms) distortion not greater than 5 or 6 per cent.

In most a-c–d-c radio sets, the screen-grid and plate voltage are taken from the plus end of the power supply, the screen-grid connection being made directly while the plate supply loses some direct voltage due to drop in the output transformer. Under such conditions, with screen-grid voltage somewhat higher than plate voltage, the distortion is apt to be considerably greater than when the plate voltage is equal to or greater than the screen voltage. For this reason the final design of tubes for a-c–d-c sets should be made partially in view of distortion measurements made at, for example, 105 volts at the plate and 110 volts on the screen grid.

36. Converter Tubes. A converter tube is an electron tube which operates as a converter or first detector in a superheterodyne receiver and, distinct from a mixer,

supplies its own local oscillator signal. Some tubes employ two electron streams so that the tube is actually an oscillator and mixer combined; each part may be considered as a triode, pentode, etc., and will not require special mention here.

The pentagrid converter employs a single electron stream, the plate current being varied in magnitude at oscillator frequency by the signal on g_1, and by the r-f signal on g_4. The intelligence contained in the r-f signal is then obtained as a modulation of the i-f signal whose frequency may be the sum of or difference between the oscillator and r-f carrier frequencies.

In the usual pentagrid converter there are a cathode, five grids, and an anode. The second grid frequently comprises a pair of heavy wires disposed between the side rods supporting g_1 and g_3, and is conventionally called a *hairpin* grid. Usually g_3
FIG. 13. Circuit for measuring conversion transconductance of pentagrid converter tubes. (1, 2) Variacs. (3) Step-down transformer, 5-volt secondary. (4) Step-down transformer, 25-volt secondary. (5) A-c voltmeter, 5 volts full scale. (6) Resistor of value specified for tube. (7) D-c milliammeter, 1.0 ma full scale. Adjust current by (2) to rated value of tube under test. (8) Dropping resistor; use when specified. (9) Laboratory-type multirange milliammeter.

and g_5 are tied together internally, as both are used as screens, while g_4 is a variable-pitch control grid upon which the r-f signal is introduced. In operation, g_1 and g_2 are used in the same way as the grid and plate of an ordinary triode oscillator with g_1 self-biased.

The conversion transconductance g_c of a converter tube is the quotient of the alternating plate current component of intermediate frequency by the alternating voltage at the signal grid under a standard condition of oscillation. The characteristic is ordinarily measured with a 60-cycle signal frequency, and since this measurement is not commonly given in textbooks, it is described here. The circuit is shown in Fig. 13.

It will be recognized that if the oscillator and signal frequencies are equal, the difference frequency in the plate circuit will be zero, and that the plate current will be greater when the two signals are in phase than when they are applied 180 deg out of phase. Therefore, the difference in direct plate current which may be measured when the phase relation of the two signals is reversed, divided by twice the peak value of alternating voltage applied to g_4, is the conversion transconductance g_c.

Since it is neither convenient nor desirable to have the tube operating as an oscillator to provide both signals for such a measurement, the signal is taken from the 60-cycle supply as indicated in the figure. The magnitude of the signal to g_1 is commonly adjusted for each tube so that the grid current will have the value rated for the oscillation condition at the specified value of the grid resistor 6 in Fig. 13.

A bucking circuit is placed in the plate lead so that the plate current difference Δi_b, obtained when the reversing switch is thrown, may be read accurately; the current in the meter is first adjusted to zero when the signals are out of phase. The conversion transconductance will, with such a test, be given by the relation

$$g_c = \Delta i_b / 2E_{g4}\sqrt{2}$$

where E_{g4} is the rms voltage applied to g_4. With most tubes it is convenient to set E_{g4} at 0.354 volt so that g_c in micromhos will be numerically equal to Δi_b when the latter is read in microamperes. In any event, E_{g4} should be held to a low value, and the wave form of the line voltage should be reasonably free of distortion. The usual precautions with respect to constancy of direct supply voltages and the adequacy of by-passing are to be observed.

A most important design feature of the pentagrid converter is the variable-pitch control grid, g_4. This grid operates at a negative voltage, the magnitude of which is controlled by the a-v-c circuit of the receiver. A curve showing g_c plotted against e_{c4} should, therefore, resemble in a general way the shape of the g_m-e_c curve of the pentode amplifier used in the same equipment. If the winding of g_4 were constant, the g_4-plate transconductance, hence the conversion transconductance, would be sharply peaked at a value of e_{c4} which would depend upon the pitch and upon the dimensions and voltage of g_5. Furthermore, if the grid were made with a number of sections having different pitches, the curve would be full of humps, each hump corresponding to a certain pitch. The reason why this would be so is obvious in the light of what has been said of the suppressor-grid voltage-plate current relations in a pentode. The conditions in the region between g_3 and g_5 of a pentagrid converter are similar in that a negative grid has a positive electrode each side of it, so that control consists in turning back a portion of the electrons that approach it.

In view of the fact that each section produces a peak in g_c at a different value of e_{c4}, if a smooth curve is to be obtained the pitch of g_4 must be varied almost continuously throughout its length. In practice, the most widely spaced turns are in the middle of the grid, the spacing between turns being decreased with a reasonable degree of uniformity from the middle to the ends. The turns at the ends are spaced to result in maximum g_c being obtained at a value of e_{c4} about 1 volt less negative than the bias value designed for minimum signal, *i.e.*, at $e_{c4} = -2.0$ volts in most receiving tubes.

Sometimes control grids g_4 are found having several turns of constant pitch at each end. This practice can be overdone, and it results in a very steep slope in the curve of g_c against e_{c4} in the region of -3 volts with considerable spread in the value under standard test conditions, usually $e_{c4} = -3.0$.

A further result of improper design of g_4 is an abnormally large shift in g_c during the first 50 or 100 hr of operation. In the section on triodes, attention was called to the manner in which the internal correction voltage ϵ influences i_b and g_m, and to the fact that, by proper aging, ϵ can be reduced to a value low enough so that, when the tube is designed for such a value, the deterioration of the characteristics on life is considerably reduced. In a pentagrid converter the slump in g_c during early life is due almost exclusively to change in the contact potential of g_4. Because the grid is so far from the cathode, it does not respond readily to the 30-sec hot shot described for triodes, so that recourse must be had to such help as can be obtained by spraying the grid and by avoiding designs that result in too steep a slope in the g_c-e_{c4} curve in the region of 3 to 5 volts bias.

37. Interelectrode Capacitance. The interelectrode capacitances of electron tubes may be computed to the extent that the end or edge effects may be ignored. The shunt capacitances added by the stem, base, etc., are usually taken by measurement of the complete tube, then of the base and stem with tube electrodes removed. For adjustment of capacitances due to stem and base, a judicious choice of basing arrangement will in many cases be indicated, as well as arrangement and spacing of lead wires in the stem.

The basic formulas, as in the case for perveance, are given first for diodes, then

expanded for tubes having grids. The dielectric constant is unity for vacuum, hence does not appear in the formulas.

For parallel planes,

$$C = 0.0885A/x \qquad \mu\mu f \tag{57}$$

where A = area, sq cm
x = spacing, cm

For coaxial cylinders,

$$C = 0.2416L/\log_{10}(r/r_0) \qquad \mu\mu f \tag{58}$$

where L = length, cm
r and r_0 = anode and cathode radii, respectively

Approximate compensation for edge effects can be made in Eq. (57) by increasing A by one-half the product of periphery and spacing and in Eq. (58) by increasing L by $(r - r_0)$.

For tubes having grids, the cold capacitances are readily expressed in terms of the capacitance between conducting sheets located at the grids and the capacitances between the actual grids and the conducting sheets.

In the *triode*, the conducting surface that replaces the grid, here called the *grid surface*, has capacitance C_1 between it and the cathode, and capacitance between the grid surface and anode is C_2. The grid and grid surface are coupled by C_g, related to C_2 and mu by

$$\mu = C_g/C_2 \tag{59}$$

where μ is taken to be μ_{pgk}.

C_1 and C_2 are calculated from Eq. (57) or (58) depending upon shape, x being the distance between parallel planes, r_0 and r being the inner and outer radii of coaxial cylinders.

The equivalent network gives, for the cold triode, the input capacitance

$$C_{\text{in}} = \frac{\mu(C_1 + C_2)}{\mu + 1 + (C_1/C_2)} \tag{60}$$

the output capacitance

$$C_{\text{out}} = \frac{\mu C_2 + C_1}{\mu + 1 + (C_1/C_2)} \tag{61}$$

and the grid-plate capacitance

$$C_{gp} = \mu C_2/(\mu + 1) \tag{62}$$

For the *tetrode*, C_2 is the capacitance between g_1 and g_2 surfaces, C_3 is the capacitance between the g_2 surface and plate, and the capacitance between the g_2 surface and actual g_2 is $C_{g2} = \mu_2 C_3$, where μ_2 is the amplification factor of the tube when g_1 is omitted. The cold capacitances with g_2 grounded through a by-pass having negligible reactance are

$$C_{\text{in}} = \frac{\mu_1(C_1 + C_x)}{\mu_1 + 1 + C_1/C_x} \tag{63}$$

where $C_x = \dfrac{C_3(\mu_2 + 1)}{1 + C_3(\mu_1 + 1)/C_2}$
μ_1 = triode mu, plate at screen-grid surface
μ_2 = triode mu, g_1 omitted

$$C_{\text{out}} = \frac{\mu_2 C_3 + C_y}{\mu_2 + 1 + (C_y/C_3)} \tag{64}$$

where $C_y = \dfrac{\mu_1 C_2}{\mu_1 + \mu_1(C_2/C_1) + 1}$

$$C_{g1-p} = \frac{\mu_1 C_2}{1 + \mu_1(C_2 + C_x)/C_z} \tag{65}$$

where $C_z = \dfrac{C_2^2 + \mu_2 C_1 C_3}{C_1 + \mu_2 C_3}$

For *pentodes*, the corresponding capacitances are taken by replacing g_3 with the grid surface which is coupled to g_3 through the capacitance $\mu_{4p}C_5$. However, the resultant value of grid-plate capacitance is smaller than the actual end effects even with practicable shielding. For most purposes the input capacitance may be taken as that of the triode with plate at g_2, and the output capacitance as that of a triode with the cathode at g_2, since g_2 will be by-passed to ground.

38. Effect of Space Charge. The presence of electrons in the space between the electrodes increases the capacitance, since the field at the anode is greater than when the interelectrode space contains no electrons. For parallel plates in which one electrode is a cathode and the other a plate to which a space-charge-limited current flows, the capacitance is $\frac{1}{3}$ greater than in the charge-free condition given by Eq. (57). This, however, is not to be taken as meaning that the susceptance increases by the same factor; in fact, the susceptance is lower in the space-charge-limited diode than between the charge-free electrodes except at extremely high frequencies. Thus, for the cold tube, the admittance y for a diode having plane electrodes is

$$y = jb_0 = j\omega C \qquad (66)$$

while for the space-charge-limited diode,

$$y = g_0 + j(\tfrac{3}{5}\omega C) \qquad (67)$$

where $g_0 = 3i/2e_p$, the zero-frequency conductance
ω = angular frequency
C = cold capacitance

In tubes having grids the characteristics are all modified by space charge, especially in the cathode-grid region. For example, Eq. (67) applies to the admittance of the equivalent diode-anode of a tube having plane electrodes, so that an approximation of the altered transadmittance y_{pg} may be written

$$y_{pg} \simeq g_m\,[\cos\,(\tfrac{11}{15}C_1 + C_2) - j\omega\sin\,(\tfrac{11}{15}C_1 + C_2)] \qquad (68)$$

where C_1 is the cold capacitance between cathode and grid plane and C_2 is that between grid plane and plate. It is to be assumed that $e_b \gg e'$, the equivalent diode voltage, so that space-charge effects beyond the grid may be disregarded for a first-order approximation. A more accurate expression for the transadmittance is obtained from the equations that include the effects of transit time, shown in subsequent paragraphs.

39. Transit-time Effects in Nonmicrowave Tubes. At frequencies where the time of flight of an electron between a pair of electrodes is an appreciable part of the time of one cycle of the alternating voltage between the electrodes, the characteristics are no longer described by the simple relations that have been given up to this point.

One visualizes an electron as being emitted from the cathode of an electron tube at a relatively low velocity, then being accelerated by the field of another electrode to a relatively high velocity. Regardless of the path taken or of the velocity it may have had at some previous position in flight, the kinetic energy possessed at any instant is the product of its charge by the *net* change in potential. The velocity in the direction of travel will be

$$v = (2Ve/m)^{1/2} \qquad (69)$$

which, in practical units, is

$$v = 5.93 \times 10^7 V^{1/2} \quad \text{cm/sec} \qquad (70)$$

where V is the potential, e and m being, respectively, the charge and mass of an electron.

When the electron passes from a plane cathode to a plane-parallel anode of a diode and the current is space-charge-limited, transit time will be

$$T = 3x/v \quad \text{sec} \qquad (71)$$

where x is the distance between the electrodes and v is the final velocity given by Eq. (70). Where the current is not space-charge-limited, the transit time is lowered, the value under the condition of zero space charge being two-thirds that given by Eq. (71).

The *transit angle* θ of the region between two electrodes of a tube is the product of the transit time T of an electron through the region and the angular frequency ω of the alternating voltage between the electrodes. For a diode,

$$\theta = \omega T \qquad \text{radians} \tag{72}$$

The *impedance* z of the plane diode when the electron current is space-charge-limited is given by Llewellyn[1] in the form

$$z = (12r_0/\theta_1^4)[2(1 - \cos\theta_1) - \theta_1 \sin\theta_1] \\ -j(12r_0/\theta_1^4)[(\theta_1^3/6) + \theta_1(1 + \cos\theta_1) - 2\sin\theta_1] \tag{73}$$

where $r_0 = de_p/di = \frac{2}{3}(e_p/i)$ at very low frequency.

It is generally more useful to take the reciprocal of Eq. (73) so that the admittance of the gap is had. Thus if Eq. (73) is abbreviated in the form

$$z_{11} = r + jx_1 \tag{74}$$

the reciprocal or admittance will be

$$\begin{aligned} y &= \frac{1}{z} = \frac{r^2}{r^2 + x^2} + j\frac{x^2}{r^2 + x^2} \\ &= g + jb \end{aligned} \tag{75}$$

It is noted that the zero-frequency resistance r_0 is a coefficient in both the resistive and reactive parts of Eq. (74); similarly, the zero-frequency conductance g_0 is part of g and b of Eq. (75). From Table 4 giving values of g/g_0 and b/g_0, the admittance at higher transit angles may be found for values of g_0 and θ_1. Thus, if $\theta_1 = \pi/2$, the admittance $y = 0.9418g_0 + j0.4757g_0$.

Table 4. Values of g/g_0 and b/g_0 Space-charge-limited Diode

Radians	g/g_0	b/g_0	Radians	g/g_0	b/g_0
0	1.000	0	7.07	−0.189	2.981
0.4	0.996	0.120	7.2	−0.211	3.087
1.0	0.977	0.301	7.33	−0.228	3.196
1.4	0.954	0.423	$5\pi/2$	−0.246	3.645
$\pi/2$	0.942	0.676	8.4	−0.168	4.096
1.8	0.923	0.547	8.64	−0.106	4.273
$3\pi/4$	0.867	0.723	9.0	−0.004	4.499
2.8	0.811	0.867	3π	+0.135	4.709
π	0.760	0.982	10.0	+0.264	4.906
3.6	0.681	1.143	10.21	+0.290	4.964
4.0	0.603	1.291	10.47	+0.306	5.033
$3\pi/2$	0.439	1.579	11.0	+0.287	5.177
5.2	0.310	1.802	11.52	+0.215	5.351
5.6	0.197	2.005	11.78	+0.165	5.454
2π	0.000	2.409	12.04	+0.111	5.570
6.8	−0.134	2.773	4π	0.000	5.839

It should be noted that, in Table 4, the value of b/g_0 for θ_1 is zero. This is not, of course, to be taken as meaning that the susceptance can be taken as zero for extremely low transit angles. As the transit angle approaches zero, the admittance approaches

[1] Llewellyn, F. B., and L. C. Peterson, Vacuum Tube Networks, *Proc. IRE*, **32**, 144, March, 1944.

asymptotically the value

$$y_{(\theta\to 0)} = g_0 + (3\theta/10)g_0 = g_0 + j(3/5)\omega C \quad (76)$$

where C is the cold capacitance.

In Table 4 it will be observed that g/g_0 is negative for values of θ_1 between $\theta_1 = 2\pi$ and about 9.0 radians, reaching a value of -0.2464 at $\theta_1 = 5\pi/2$. It is this fact that makes oscillation possible in the Llewellyn diode, for if the circuit is adjusted to have an angular frequency ω and the plate voltage is adjusted by Eq. (71) so that $T_1 = 5\pi/2\omega$, oscillations will be produced, provided the shunt conductance of the external circuit is not greater than $+0.2464g_0$.

40. Transit Angle Effects in Multigrid Tubes. In triodes and in tubes having more than one grid, the transit angles in all regions affect the characteristics of the tube. A full discussion is found in the Llewellyn reference. The manner in which the characteristics of some tubes are affected will be seen in the results given below. These equations may be taken as first-order approximations when they are restricted as follows:

1. The electrodes are parallel planes, edge and lead effects ignored.
2. The cathode current is space-charge-limited, and the virtual cathode is assumed to be at the real cathode.
3. Space charge in the region beyond the control grid is assumed to be negligible.
4. The control grid draws no current from the electron stream.

The transit angles will be taken to have the following values:

Region 1. For the region between the cathode and the first electrode, the transit angle will be that given by Eqs. (71) and (72) for the space-charge-limited diode and may be expressed in the form

$$\theta_1 = \omega T_1 = \omega x_1 \times 10^{-7}/2\sqrt{e'} \quad (77)$$

where x_1 is the cathode-grid spacing and e' is the potential of the equivalent grid plane.

Region 2. For the region between the grid and plate of a triode,

$$\theta_2 = \omega T_2 = 3.37\omega x_2 \times 10^{-8}/(\sqrt{e'} + \sqrt{e_b}) \quad (78)$$

For a tetrode,

$$\theta_2 = \omega T_2 = 3.37\omega x_2 \times 10^{-8}/(\sqrt{e'} + \sqrt{e''}) \quad (79)$$

where x_2 is the spacing between control and screen grids and e'' is the voltage of the equivalent screen-grid plane and may be taken to have the value

$$e'' = (\mu_2 e_{c2} + e_b)/[1 + \mu_2 + (x_3/x_2)] \quad (80)$$

where x_3 is the screen grid-plate spacing and μ_2 is the amplification factor of the tube when g_1 is omitted. The error is usually not great if e'' is taken as e_{c2}, provided the value of μ_2 is high.

Region 3. For the region between g_2 and anode,

$$\theta_3 = \omega T_3 = 3.37\omega x_3 \times 10^{-8}/(\sqrt{e''} + \sqrt{e_b}) \quad (81)$$

Although it would be understood that the equivalent diode controlling voltage e' is to include the internal correction voltage ϵ, the error is not great if it is not included in the screen grid and anode potentials; thus the direct cathode current may be expressed

$$i_k = G\left[\frac{\mu_1 e_g + e''}{\mu_1 + 1 + 4/3(x_2/x_1)}\right]^{3/2} = G(e')^{3/2} \quad (82)$$

where G is the perveance and e_g is the voltage applied to the control grid plus the internal correction voltage.

For triodes,

μ_1 = amplification factor
e'' = plate voltage e_b

For tetrodes,

μ_1 = triode amplification factor
e'' = equivalent voltage at screen grid, taken as e_{c2} where μ_2 is high

The total conductance di_k/de' at zero frequency is taken to be

$$g_0 = \tfrac{3}{2}G(e')^{1/2} = \frac{3}{2} i_k \left[\frac{\mu_1 + 1 + \frac{4}{3}(x_2/x_1)}{\mu_1 e_g + e''} \right] \tag{83}$$

When the transit angles in both regions of the triode and all three regions of the tetrode are just great enough to be significant, the grid-plate transconductance may be taken to have the following values:

For the triode,

$$g_m = \frac{g_0 \mu}{\mu + 1 + \frac{4}{3}\frac{x_2}{x_1}\left(1 + \frac{1}{2}\frac{\theta_2}{\theta_1}\frac{\sqrt{e'} + 2\sqrt{e_b}}{\sqrt{e'} + \sqrt{e_b}}\right)} \tag{84}$$

For the tetrode,

$$g_m = \frac{i_b}{i_k} \frac{g_0 \mu_1}{\mu_1 + 1 + \frac{4}{3}\frac{x_2}{x_1}\left(1 + \frac{1}{2}\frac{\theta_2}{\theta_1}\frac{\sqrt{e'} + 2\sqrt{e''}}{\sqrt{e'} + \sqrt{e''}}\right)} \tag{85}$$

where μ_1 is the triode mu.

The *grid-plate transadmittance* y_{pg}, of which the real part is the transconductance, may be expressed in terms of the l-f values given by Eqs. (84) and (85).

For moderately low frequencies,

$$y_{pg} \simeq g_m(\cos\phi - j\sin\phi) \tag{86}$$

$$\text{where } \phi = \frac{\theta_1\left[\frac{11}{30}(\mu_1 + 1) + \frac{7}{18}\frac{x_2}{x_1}\right] + \theta_2\left[1 + \mu_1 + \frac{4}{3}\frac{x_2}{x_1}\left(1 + \frac{1}{8}\frac{\theta_2}{\theta_1}\frac{3\sqrt{e'} + 5\sqrt{e''}}{\sqrt{e'} + \sqrt{e''}}\right)\right]}{1 + \mu_1 + \frac{4}{3}\frac{x_2}{x_1}\left(1 + \frac{1}{2}\frac{\theta_2}{\theta_1}\frac{\sqrt{e'} + 2\sqrt{e''}}{\sqrt{e'} + \sqrt{e''}}\right)} + \frac{1}{3}\theta_3\left(\frac{\sqrt{e''} + 2\sqrt{e_b}}{\sqrt{e''} + \sqrt{e_b}}\right) \tag{87}$$

For very high values of transit angle,

$$y_{pg} \simeq \frac{i_b}{i_k} g_0 \left(\frac{\mu_1}{1 + \mu_1 + x_2/x_1}\right)\left[\frac{\sqrt{e''} - P\sqrt{e_b}}{j(\theta_2/2)(\sqrt{e''} + \sqrt{e_b})}\right] Q \tag{88}$$

where $P = \cos\theta_3 - j\sin\theta_3$
$Q = \cos(\theta_1 + \theta_2) - j\sin(\theta_1 + \theta_2)$

For the triode, the expressions are obtained directly from Eqs. (87) and (88) by setting $e'' = e_b$ and letting θ_3 approach zero so that the second term of Eq. (87) drops out and the bracketed term of Eq. (88) becomes unity; the equivalent-triode mu, μ_1, then becomes the triode amplification factor μ.

For the pentode, the real part of the transadmittance may be taken as substantially

that of a tetrode, the phase being increased by the increase in transit angle between the screen grid and plate of the pentode as compared with that in the tetrode.

CATHODE-RAY TUBES

Cathode-ray tubes ordinarily employ indirectly heated, oxide-coated cathodes. The electrodes are usually made of stainless steel or nickel. The magnitude of the electron beam is controlled by means of a grid comprising essentially a disk having a single hole. The beam may be focused on the screen by either an electrostatic lens or a magnetic lens. Similarly, the beam or beams may be deflected on the screen by either electric fields or magnetic fields.

In the following sections some of the more important principles of construction and operation will be outlined as they apply to cathode-ray tubes in general, including television tubes for color display. No attempt is made to distinguish between various kinds of cathode-ray tubes; color tubes are not discussed in detail because they are in an evolutionary stage and are likely to remain so for many years.

41. Focusing. In most cases it is easier and more economical to use electric focusing and deflection, as is done in oscillographic and low-price television equipment. Magnetic focusing produces a better spot, and magnetic deflection results in less deflection defocusing. This permits wider angle deflection, hence a shorter tube. Thus, although somewhat more expensive, all-magnetic tubes are at present preferred in high-quality television receivers.

The focusing and deflection of electrons in a cathode-ray tube depend upon the forces exerted on them by the electric and magnetic fields through which they move between cathode and screen. These forces are vectors, and although the quantitative relations that will be given are in scalar notation, it should be understood that the reference axes must be chosen to make this convenience valid. Thus the electric force $f_{(e)}$ is

$$f_{(e)} = -eF$$

where e is the charge and F the field. Taking the perpendicular axes x, y, and z, the forces will be

$$f_x = edV/dx$$
$$f_y = edV/dy$$
$$f_z = edV/dz$$

where f_x is the force in the x direction, $-dV/dx$ is the field in the x direction, etc.

Similarly, the magnetic force is

$$f_{(m)} = Bev$$

where B is the magnetic field perpendicular to the path of the electron and v is the electron velocity. The forces in the three directions will be

$$f_x = e[B_z(\partial y/\partial t) - B_y(\partial z/\partial t)]$$
$$f_y = e[B_x(\partial z/\partial t) - B_z(\partial x/\partial t)]$$
$$f_z = e[B_y(\partial x/\partial t) - B_x(\partial y/\partial t)]$$

where the Bs are the magnetic field components in the subscript directions and the derivatives are the velocity components in the indicated directions.

While the application of these principles to the design of a satisfactory focusing system is a highly specialized problem, the deflection for small angles may readily be derived.

42. Electrostatic deflection, neglecting edge effects, requires that the deflection field be the quotient of the voltage between the plates by the distance between them. The force will be applied during the time $t = l/v$, so that the electrons emerge at an angle given by

$$\tan \phi = (l/2)(F/V_0) \tag{89}$$

where ϕ = angle of deflection
l = effective length of deflection system
F = average field perpendicular to axis
V_0 = beam potential

Neglecting second-order effects, the displacement d of the spot on the screen may be written

$$d \simeq (Ll/2x)(e_d/e_0) \tag{90}$$

where L = distance from center of deflection system to screen
x = separation between deflection plates
e_d = voltage between deflection plates
e_0 = voltage between deflection system and cathode

43. Magnetic Deflection Systems. Here it is assumed that the electrons enter the deflection system along the z axis. With the magnetic field perpendicular to the z axis or axis of the tube, the electrons will have a force applied in the $+y$ direction at first, then in the $+y$ and $-z$ directions as the velocity component in the y direction becomes finite. Therefore, the electrons describe a circular path in a plane perpendicular to the applied magnetic field, so that they emerge at an angle ϕ from the axis given by

$$\phi = (lB_x/V_0)\sqrt{e/2m} \tag{91}$$

where B_x is the field perpendicular to the axis, m is the mass, and e the charge. For practical purposes, the displacement of the spot on the screen will be

$$d \simeq LlB/3.37\sqrt{V_0} \tag{92}$$

where B is the field in gausses.

44. Defocusing Effects. Both systems have inherent defects due to the fringing fields at the edges of the focusing system operating on a beam of finite diameter, the net effect being known as *deflection defocusing.* Some compensation is achieved through careful attention to the shapes of the deflection fields. In general, deflection distortion is minimum when the length of the deflection system is maximum, the limit being to a considerable degree a compromise between distortion, mechanical size, and circuit loading.

45. The Ion Trap Gun. The beam of a cathode-ray tube consists almost entirely of electrons, but there is present in addition ions of various elements in the tube, the most prevalent generally being that of oxygen, O_2^-. Where the ions strike the screen, they cause a reduction in the luminous efficiency of the phosphor. In a system employing electrostatic focusing and deflecting, the ions are focused and deflected in the same manner as are the electrons, since the deflection is independent of mass, as seen by Eq. (90). With the spot continuously moving, the effect of the ions is spread more or less uniformly over the screen so that the decrease in luminous efficiency is not great. However, where the beam is electrostatically focused and magnetically deflected, the ions and electrons reach the deflection system moving together on or near the axis of the tube. The angle of deflection, as shown by Eq. (90), is inversely proportional to the square root of the mass, so that, for instance, an oxygen ion O_2^- is deflected only by an amount $d/\sqrt{32 \times 1{,}850}$, which would be about 0.01 in. when the spot due to the electron beam is displaced 3 in. The result is that in time a dead spot, or *ion burn*, occurs in the center of the screen.

Ion burns are prevented in tubes employing magnetic deflection when an ion trap gun is used and are inhibited by the use of an aluminum screen backing.

In an ion trap gun the beam is first formed, then bent by means of a constant magnetic field. The electrons are then allowed to pass on toward the screen, while the ions, which were substantially undeflected, are captured in the electrodes or on the neck of the bulb. This requires that the tube be provided with a bend in the gun or neck of the bulb.

It is evident, however, that if a magnetic field and an electric field are applied at

right angles to each other at substantially the same location on the axis, the ions may be separated from the beam when the fields are adjusted to produce equal but opposite deflections *for electrons* by Eqs. (90) and (91). Although such an arrangement is not readily achieved in practice, guns have been made in which the electron path does not move far off the axis of the tube and the ions are substantially all removed from the beam.

Table 5

RETMA No.	Sylvania type No.	Material	Fluorescent color	Phosphorescent color	Persistence	Approx avg particle size, μ	Remarks	Application

46. Aluminum-backed Screens. The aluminum screen backing consists essentially of a very thin film of aluminum laid flat over the screen. Its principal purpose is to reflect the light emitted by the phosphor so that it is passed back through the face of the tube where it may be seen, thus improving the over-all efficiency. While the loss in energy of an electron in passing through the aluminum backing may be of the order of a few thousand electron volts, the over-all efficiency of the aluminum-backed screen is greater than the unbacked screen at beam potentials greater than about

5 kv. The aluminum backing also has an inhibiting effect on ion burning. It is produced by volatilizing aluminum metal onto a thin membrane stretched across the phosphor, then removing the membrane by thermal decomposition. The membrane is produced by first placing enough water in the bulb to cover the faceplate, then adding a small amount of nitrocellulose diluted to 3 per cent in amyl acetate; when the solvent evaporates, the water is poured out from under the solidified film.

47. Phosphors. The coating of the screen in a cathode-ray tube is called a ***phosphor*** and the process by which part of the energy of the bombarding electrons is converted to light is called *fluorescence.* When the beam is cut off, the light output due to *phosphorescence* usually decays rapidly at first, then more slowly.

Most of the phosphors used in commercial tubes are sulfides or silicates activated with silver or manganese, although titanium and copper are sometimes used as activators. Table 5 shows the composition and characteristics of phosphors standardized by the Radio-Electronics-Television Manufacturers Association. It should be noted that some phosphors of the same general type, such as the P-22 phosphors used in color TV tubes, are made in several varieties and are sold according to the manufacturer's type numbers; Sylvania type numbers are given in the second column to illustrate commercial practice.

48. Screening. The process of settling the phosphor on the faceplate of the cathode-ray tube is called *screening.* Details of practices vary among manufacturers and among tube types; an outline of the procedure followed for a 21-in. black-and-white TV picture tube follows as an illustration.

1. Place 600 cc of 1 per cent barium acetate in bulb; then add 22 liters of water.
2. Add 1,100 cc of 0.5-normal potassium silicate. Simultaneously add phosphor suspension, consisting of 100 g of phosphor ball-milled in 300 cc of water, then diluted to working consistency.
3. After slight agitation to ensure mixing, the suspension is allowed to settle, the water is poured off, and the bulb is then baked to solidify the screen.

Most phosphors produce maximum light output when the amount of phosphor used is equivalent to about 4 or 5 mg per cm^2, although there are exceptions. The phosphor manufacturer ordinarily is able to provide a recommended figure.

All water used for solutions and suspensions in processing cathode-ray tubes must be either distilled or deionized, as the salts normally occurring in tap water produce undesired effects. Copper salts cause a shift in screen color; iron salts cause degeneration of fluorescence; other compounds contribute to emission failure or the occurrence of gas.

The potassium silicate bonds the phosphor particles together and to the faceplate of the tube. The barium acetate promotes jelling of the silicate.

In tubes operated with beam potentials in excess of 12 kv, it is common practice to use coated phosphors in order to prevent burns due to ion bombardment. The coating process consists in precipitating a thin film of silica on the phosphor particles. This operation is normally performed by the phosphor manufacturer. Silica coating usually results in a decrease in light output of about 5 per cent.

CHAPTER 8

MICROWAVE TUBES

By G. C. Dalman[1]

1. Introduction. The field of microwave tubes today covers a vast and rapidly expanding area, and to expound it fully would be a formidable task. The scope of this chapter has therefore been limited to a concise presentation of the physical picture of microwave-tube behavior and a description of the important present-day microwave-tube types.

In the following paragraphs a discussion of microwave-tube theory encompassing three categories is given: the electron beam of the tube, the tube microwave circuit, and the interaction phenomena which occur between the beam and the circuit. The discussion is limited to those portions of the theory already proved successful, and only enough of the underlying physics will be given to make the physical picture of the operating principles understandable.

2. Energy-conversion Processes. The basic problem in microwave tubes, as with other amplifier, oscillator, and frequency-multiplier tubes, is to convert energy from a d-c power supply into useful r-f energy. In general, this is accomplished by arranging, within the tube, a suitable interaction between an electron beam and an electromagnetic field. In one method commonly used, electrons which have received high kinetic energies by acceleration through a d-c field are caused, by proper design of tube structure and tube circuit, to be decelerated by an electromagnetic field which has been set up by the r-f voltage to be amplified or generated. The energy lost by the electron due to this deceleration is, by conservation of energy, gained by the r-f field. For the ideal case of 100 per cent energy transfer, the electrons are slowed down to zero velocity and all the kinetic energy of the electrons is converted to useful r-f energy.

An alternative method for converting the d-c power-supply energy into useful energy is to arrange an interaction structure in which the electrons of the beam pass through a d-c field without a change in the kinetic energy of the electrons. In this case the d-c potential energy is said to be transferred into useful r-f energy.

All microwave tubes are based on either or both of these types of interaction, and the chief differences among them originate in the particular manner in which the electrons are allowed to interact with the electromagnetic field, the type of electron beam used, and the arrangement of the electromagnetic circuit. In the following paragraphs the important differences are described.

ELECTRON BEAMS

In general, an electron gun is a device for providing a beam of high-velocity electrons arranged in a particular geometrical shape, *e.g.*, cylindrical, ribbon, hollow tube, etc. It is comprised usually of a properly shaped cathode, an anode, and a means for focusing the beam to the desired shape. Usually no r-f field exists in the cathode-anode space. If we classify, however, the cathode-anode region of the magnetron and microwave diode and triode as electron-gun structures, these types are notable exceptions. A large variety of gun structures are used in present-day microwave tubes, the most important of which will be described to illustrate, in a general way, some of the many practical considerations in selecting a beam for a microwave tube. Considered briefly are focusing methods in the accelerating and drift regions of the gun, limitations

[1] Cornell University.

imposed by the electron emitters used, and a summary of some important phenomena observed in electron beams.

3. Cathode Considerations. Most microwave tubes are designed to deliver moderate power (20 mw minimum) or high power (up to 40 megawatts pulsed), and for these tubes the electron beams used are characterized by high-voltage high-current operation. For c-w-operated tubes, beam voltages and beam current densities range from 10^2 to 10^4 volts and 0.050 to 50 amp per cm^2, respectively, and for low-duty-cycle pulse operation, beam voltages and beam current densities as high as 400 kv and 10 amp per cm^2 are used. Important problems are the limitations imposed by the electron-emitting source such as the maximum allowable current density and effects of ion bombardment.

Three types of electron sources for beams are in common use: oxide-coated nickel, pure metal, and thoria. A wide variety of dispenser types are in experimental use. The important characteristics of these electron sources are discussed below.

4. Oxide-coated Cathodes.* Long-life operation can be obtained from c-w-operated oxide cathodes operating up to about 1,500 beam volts; and for pulse operation, provided the pulse duration is kept shorter than the ionization time of the residual gas in the tube, safe operation up to 400 kv is possible. This type of cathode has the widest application, and the methods for producing them are best understood. Its chief limitation is that the safe operating current density is limited to about 0.2 amp per cm^2 maximum for c-w operation and approximately 5 amp per cm^2 maximum for pulse operation at normal operating temperatures (800 to 825°C). A second limitation is the deleterious effect of ion bombardment which occurs for high-duty-cycle operation above 1,500 beam volts. The application of the oxide cathode in microwave-tube beams, however, has been remarkably successful.

5. Pure-metal Cathodes. To permit c-w operation at high voltage (e.g., 5,000 to 10,000 volts) without ion-bombardment damage, an emitting surface consisting of a disk of high-melting-point metal such as tantalum, molybdenum, or tungsten is sometimes used. Because of the high work function of these metals it is impractical to heat the disk to emitting temperatures with conventional heaters of the type used with the oxide-coated types. It is necessary rather to use an auxiliary emitter such as a pure or thoriated-tungsten filament to bombard the opposite face with electrons. The total dissipation of this subsidiary diode is adjusted so that the temperature of the cathode-emitter material reaches the desired value.

While this type of cathode is especially insensitive to ion bombardment, the added complexity of the subsidiary diode structure and power-supply equipment makes it rather unsatisfactory. Thoriated-tungsten cathodes have been proposed but are not in commercial use.

6. Thoria-type Cathode.[1,†] At present there are two types of thoria emitters. The first is an indirectly heated type in which, following the practice of the conventional oxide cathode, a thin coating of powdered thorium oxide is formed on a base metal. Because the normal operating temperature of the cathode is approximately 1600°C, the refractory metals (tungsten, tantalum, or molybdenum) are used as base metals. The cathode operating temperature is much lower than for the pure-metal cathodes, and it is possible to design tungsten heaters to heat the thoria to 1600°C. The heater, however, must operate in the approximate range of 2400 to 2700°C which can cause short heater life due to the high evaporation rate in vacuum of tungsten at these temperatures.

The second type of thoria cathode is directly heated. This cathode is formed by molding a mixture of powdered thorium oxide with powdered tungsten or molybdenum into a suitable form (*e.g.*, cylinder) and firing at about 2000°C. Electrical and mechanical contact is made at each end of the cathode and heating is accomplished by passing a high current directly through the cathode structure.

An important advantage of the thoria cathode is its ability to withstand high-

* See also discussion of G. D. O'Neill in Chap. 7.

† Superior numbers indicate the literature references at the end of this chapter.

voltage ion bombardment. Higher pulse- and c-w-operation-current densities than are possible with conventional oxide cathodes are claimed; sufficient operating experience in commerical tubes, however, has not been accumulated to establish definite values. The thoria-type cathode, although not in widespread use, has some important applications in magnetrons and power tetrodes.

7. Miscellaneous Dispenser-type Cathodes. In recent years another group of experimental emitters[2-6] has been developed with properties intermediate between the standard-type oxide-coated emitter and the pure-metallic emitter. These can be classified roughly as dispenser types. Essentially, they contain a large amount of low-work-function semiconductor material, such as the standard-type oxide coating either uniformly or nonuniformly distributed in a porous-type plug. One surface of the plug faces the vacuum and acts as the electron-emitting source. The porous material used for the plug is generally sintered nickel or tungsten powder. During operation a large amount of active metal (*e.g.*, free barium) is produced and diffuses to the emitting surface, continuously replenishing the active metal which has been evaporated or sputtered. The chief advantages of this cathode, compared with the standard oxide cathode, are that it is much less sensitive to ion bombardment and that c-w-operation current densities of 1 to 5 amp per cm^2 are practical. This type of emitter, however, must operate about 100 to 150°C hotter than the standard oxide cathode. Usually the rate of evaporation of the active metal is high and sometimes undesirable phenomena such as grid emission result.

Improvements in microwave-tube performance can be expected as improvements in the dispenser-type cathodes are made.

Other types of cathode, such as the lanthanum boride cathode, have been proposed but the practical importance of these has not yet been established.

ELECTRON GUNS

8. Principal Gun Types. In broad terms, electron guns can be classified as ***convergent***, *parallel-flow*, and *divergent* types. Convergent guns find their application where very high values of beam current densities are required as in many klystrons and traveling-wave tubes. They are used where the beam current densities are greater than the allowable safe values available directly from the cathode surface. The parallel-flow type, simpler in structure, is used where the current densities available directly from the cathode are adequate, as in microwave diodes and triodes and some klystrons and traveling-wave tubes. Although not in as widespread use as the convergent type, improvements in high-current-density cathodes, such as the dispenser type, will increase the importance of parallel-flow guns. The divergent gun at the present time has no commercial application.

For conciseness, the discussion has been limited here to the convergent-type gun, the most important of the three types. The discussion should serve to illustrate in a general way the important beam-operating characteristics and problems encountered. Taken up are the basic structures of the principal gun types, a discussion of the method of focusing the beam in the cathode-anode (accelerating) region, and methods for maintaining the beam shape in the field-free "drift" space. A limited discussion of some special beam phenomena is also included.

9. Gun Structures. The most common type of convergent gun, usually called a "Pierce gun,"[7] is illustrated schematically in Fig. 1. It consists of a cathode and anode which are portions of a spherical diode, and a focusing structure. For large values of the semiangle θ, the anode often takes the form of a spherically shaped tungsten mesh, and for low semiangles, a flat-anode grid is often satisfactory. Gun microperveances* in commercial-type tubes are as high as 15, and gun semiangles as high as $\theta = 35°$ have been used. An important feature of the Pierce gun is that the current density is uniform across the cathode and anode surfaces.

* Microperveance is 10^6 times the beam current (amperes) divided by the $3/2$ power of the beam voltage (volts$^{3/2}$).
FIG. 1. Schematic diagram of a "Pierce" gun.
FIG. 2. Empirically designed gun (2K25). FIG. 3. Gridless-anode gun.

Another convergent-type gun which is of empirical design is shown in Fig. 2. This gun was widely used in some of the early reflex klystrons.[8]

In many applications it is desirable to eliminate the anode grid. Several gridless-anode guns have proved successful, and these are shown in Figs. 3, 4, and 5. The gun of Fig. 3 is a gridless-anode type designed[9,10] for uniform cathode-current density. Figures 4 and 5 show two high-angle empirically designed guns.[11] The gun of Fig. 3 is widely used in klystron and traveling-wave tubes, and the principal use of those illustrated in Figs. 4 and 5 has been in reflex klystrons.

FIG. 4. High-angle gridless-anode gun.

10. Focusing Methods in the Cathode-Anode Space. The focusing structures for microwave tubes of early design were determined empirically. While some of these guns have excellent characteristics, the design is determined by trial and error and is extremely laborious. These guns often suffer from the defect of nonuniform cathode-current densities. However, the guns of Figs. 2, 4, and 5 have proved very satisfactory. Once a satisfactory design is established, these guns can be scaled for higher- or lower-voltage operation.[12]

One of the most important advances in gun-design techniques has been suggested by Pierce,[7] who proposed that the focusing structure be designed to provide boundary

conditions at the outer edge of the beam which is identical to that known to exist[13] in the spherical diode shown dotted in Fig. 1. The electrons of the beam will then flow in the gun in the radial direction only as in the spherical diode. The design of the focusing structure is determined by placing a scale model of the gun in an electrolytic tank, and the shape of the focusing structure is adjusted experimentally to provide the proper boundary conditions at the beam edge.[7,13] The most easily fabricated shape of a wide variety usually possible is selected for actual use.

Transmission efficiency 95%
Perveance .... 3 microamp/volt $^{3/2}$
Current density multiplication 75
Heater power .... 3.9 watts

Beam voltage (volts)	400	500	600
Cathode current (ma)	24	33	45
Current density at cathode (ma/cm^2)	180	250	340
Current density at beam minimum (amps/cm^2)	14	19	25

FIG. 5. Heil gun. (*Bell System Tech. J.*)

11. Beam-focusing Methods. The next problem is to maintain the desired beam shape along the axis of a traveling-wave tube, through klystron cavity grids, etc., so that proper interaction between the beam and the circuit can occur. Four methods of controlling the beam shape are in use: *magnetic focusing* in which a magnetic field overcomes spreading effects due to the space-charge forces within the beam; *ion focusing* in which positive ions neutralize the space charge of the beam; *electrostatic focusing* in which space-charge spreading is corrected by a series of converging lenses; and *space-charge focusing* in which the beam follows the space-charge spread curve.

FIG. 6. Space-charge-focused beam in three-cavity amplifier.

The term space-charge focusing is used loosely since the beam is actually allowed to travel "unfocused" and the circuit is fitted to the beam. Figure 6 shows an example[14] of a tube employing a space-charge-focused beam. In this case the beam was designed so that the minimum beam diameter occurs approximately at the center of the tube. Beyond the location of the minimum beam diameter, the space charge in the beam causes the beam to diverge, making it necessary to increase the diameter of the third cavity grid. This tube is pulse-operated and the pulse duration is less than the ionization time of the residual gas within the tube.

Figure 7 shows an example of the tube employing ion focusing.[14] Ions formed by electron bombardment of the residual gas molecules in the tube are trapped within the beam neutralizing the space charge. Thus the beam travels beyond the plane of the

anode unaffected by space-charge spreading. While ion focusing has been successful in many microwave tubes, in some applications the ions introduce some undesirable second-order phenomena such as ion noise and plasma oscillations.

The third type of beam focusing utilizes a magnetic field. Early magnetically focused beams were focused by immersing the entire tube, including the gun structure, in a uniform axial magnetic field. The focusing action is based on the fact that electrons tend to follow magnetic-field lines. The method is limited to parallel-flow guns and has the disadvantage that a very large magnetic field, theoretically infinite, is required to prevent the beam from spreading. An important refinement in magnetic focusing[7,15] involves providing a particular magnetic field so that the space-charge repulsion forces and the centrifugal force of rotation are just balanced against the centripetal magnetic force on the electrons. If the beam enters the magnetic-field region properly, the outer-edge electrons spiral at constant diameter down the tube and the beam is said to have *Brillouin flow*.

FIG. 7. Ion-focused beam in a three-cavity amplifier with gridded gaps (SAS-28).

The considerations involved in the proper design of such a beam using a uniform axial field are illustrated in Fig. 8. In the ideal case, the beam is injected abruptly in a constant magnetic field from an electrostatic-type electron gun which is excluded from the magnetic field. In the actual case, however, the beam is injected gradually into the magnetic field, some magnetic flux links the cathode, the magnetic field is not completely uniform along the tube axis, and the beam may not enter the magnetic field with zero radial velocity. Wang[15] has made a complete study of this problem and with the aid of radial and axial force equations has shown how Brillouin flow can be
FIG. 8. Magnetically focused beam (shaded over).
FIG. 9. Periodic focusing structure.

obtained successfully. If the proper magnetic field and entrance conditions are not provided, the envelope of the beam will be scalloped in shape and beam interception or poor interaction usually results.

An important disadvantage to the use of magnetic focusing is the heavy and bulky permanent magnets or electromagnets required. These defects can be avoided by the use of periodic magnetic focusing.[17] Small permanent magnets, as in Fig. 9, are stacked to produce alternating-polarity magnetic fields, periodic in space. The principal application of periodic focusing has been in traveling-wave tubes.

The feasibility of periodic electrostatic focusing is definite, although no applications

can be found in commercial tubes to date. The demand for light-weight tubes of the traveling-wave types will probably lead to the development of a series of commercially available tubes.

In the following paragraphs are brief discussions of some important special beam structures and focusing methods.

12. Hollow Beams. Often the beam dimension and the physical structure of the r-f circuit of the tube are such that the interaction occurs mostly at the outer periphery of the beam, *e.g.*, as in some gridless cavity-gap klystrons, traveling-wave tubes, and
FIG. 10. Sperry hollow-beam cathode.

backward-wave oscillators. Because the center of the beam does not contribute to the output power, the use of a hollow beam can make significant improvements in tube efficiency. The simplest method for obtaining a hollow beam is to omit the oxide coating from the center of the cathode of a parallel-flow cylindrical-type immersed gun, and this type has found application in backward-wave oscillator tubes. Some progress on convergent-type hollow beams has been made by Wang and Bol,[16] but considerable work remains. An experimental hollow-beam gun having a microperveance of 10 is shown in Fig. 10.

13. Beams for Crossed-field Tubes. The gun structure and electron beam for crossed-field tubes are shown schematically in Fig. 11. A beam of electrons, properly focused in the gun region, travels perpendicular to two mutually perpendicular d-c electric and magnetic fields. A simple and systematic design procedure remains to be developed for beams for the crossed-field-tube types.

FIG. 11. Beam for crossed-field tube.

14. Modulated Beams. In many microwave-tube applications it is desired to pulse the tube to obtain a modulated signal, often of very high powers. A method often used for tubes employing non-ion-focused guns is to pulse the beam voltage directly. This has the disadvantage of requiring a high-power modulator. To overcome this difficulty an auxiliary anode grid is placed directly in the beam close to the cathode. Because of its close proximity to the cathode the beam current can be controlled by a relatively low-power auxiliary anode grid modulator. If an auxil-

iary anode of the type shown in Fig. 12 is used, little or no power is required of the modulator.
15. Low-noise Beams. An important consideration in the development of low-noise tubes is the noise properties of the beam. In effect, the noise sources in the cathode produce a noise current in the beam. This current is amplified along with the signal current introduced on the beam by the interaction circuit so that the output consists of both amplified signal and noise. An important indirect cause of this noise is the velocity spread (Maxwellian distribution) of the electrons emitted from the cathode. As a result of the interaction effects in the gun and beam region[7,17,18,19] the velocity fluctuation at the cathode becomes a current fluctuation at the anode planes because of electron-bunching action (see Interaction Theory to follow). Two other sources of noise exist: current fluctuations at the cathode surface and interception noise. The former is believed of lesser importance than the velocity fluctuation but plays an important role in determining the minimum noise figure of a microwave amplifier. *Interception noise* results when a beam strikes a part of the tube wall, *e.g.*, the gun anode.

FIG. 12. Gun with modulation anode. (*Eitel-McCullough.*)

In tubes where beam interception can be minimized, the dimensions and voltages can be arranged[18,19,20] so that the noise current at the beginning of the interaction circuit is a minimum and, consequently, the noise figure is a minimum. These guns have been developed to the point where low-noise traveling-wave tubes are now commercially available having an average noise figure of 6.5 db, over a 2,700- to 3,500-Mc band (RCA type 6861). In tube types where interception is high, such as gridded-gap klystrons, interception noise is excessive and very low noise figures are impossible to attain. For large beam-interception ratios, the beam noise is essentially equal to full shot noise.[12] Noise figures less than 4 db can be expected in the near future.

CIRCUITS FOR MICROWAVE TUBES

The circuits for microwave tubes fall into two important categories: interaction circuits and coupling circuits. Coupling circuits are devices which provide an r-f match between the input or output terminal of the tube and the tube-interaction circuit. The tube-interaction circuit is a structure which is arranged so that an electromagnetic wave on the circuit will have a component of electric field in the space occupied by the beam.

16. Interaction Structures; Resonant Cavities. The simplest form of microwave-interaction circuit is the reentrant-type cavity.[21,22] The cavity structure often takes the form of a figure of revolution about a center line such as shown schematically in Fig. 13*a*. Cavities of this type have high Qs (approximately 50 to 10,000) so that relatively small amounts of r-f power fed into the cavity will cause a high r-f voltage to appear across the cavity gap. If the cavity-gap width is made small enough so that the transit time for an electron passing through the gap is not too great, then the cavity is a useful type of interaction circuit.

A variety of similar cavity-interaction structures are also used such as doubly reentrant types and reentrant wave guides. The particular type chosen in a practical case is usually determined by factors such as band width, power-handling capabilities, and ease of manufacture.

Another important cavity-interaction circuit is the magnetron circuit shown schematically in Fig. 13*b*. This circuit consists of a group of coupled resonant cavities arranged in a ring. The behavior of the circuit can be described approximately by
(a) Reentrant cavity
(b) Magnetron cavity
(c) Strapped magnetron cavity
(d) Interdigital magnetron

FIG. 13. Resonant-cavity interaction structures.

the equivalent circuit shown in the figure. When excited at the resonant frequency two waves travel in opposite directions with a phase velocity which is some fraction of the speed of light. If an electron beam is arranged to travel in a circular motion at a speed approximately equal to the phase velocity, interaction will occur with the wave traveling in synchronism with the beam.

There are many possible operating modes of the magnetron cavity: the most commonly used is the mode in which the r-f fields across the gaps of adjacent cavities are π radians out of phase. This mode is called the π mode. Several methods are

employed to suppress other possible cavity modes, the most common of which is to connect alternate cavity gaps to two separate rings, as illustrated in Fig. 13c. Similar types of magnetron cavity structures are also used in commercial-type magnetrons.[23,24] A linear array of cavities is sometimes used in magnetron amplifiers.

FIG. 14. (a) Slow-wave structures. (b) Phase-velocity variation in the forward- and backward-wave circuits.

The cavity-interaction structures are resonant devices and standard methods are used for tuning: mechanical adjustments of the cavity gap, introduction of a plunger into the cavity to change the volume, susceptance tuning by means of a coupled cavity (*i.e.*, by frequency pulling), etc.

Interdigital Magnetron Resonant Structure. Illustrated schematically in Fig. 13d is one arrangement of an interdigital magnetron resonant structure comprised of two sets of intermeshed fingers, each set being connected to opposite poles of a single-cavity resonator not shown. Tuning is accomplished by adjustment of the cavity-resonator frequency. The fingers of the structure are used as the magnetron anode, and the cathode, also not shown in the figure, is placed at the axis of the anode.

17. Nonresonant Circuits. These consist of structures capable of propagating electromagnetic energy in several possible modes, one of which has a phase velocity slow enough to travel in synchronism with an electron beam passing through or adjacent to the structure. Useful structures are those having a component of electric field in the direction of the beam path. Thus over a long distance, the electron motion will be influenced by the field and vice versa. Many structures are capable of supporting slow waves, a few of which are illustrated in Fig. 14. The most widely used of these circuits is the helix (Fig. 17). It is clear from an inspection of the helix structure that, although the electromagnetic energy travels around the helix with the speed of light, the velocity of propagation of the axial fringe field is considerably less.

When these circuits are used in amplifiers, an attenuator is usually placed on the circuit near the input end to prevent oscillation due to reflected waves near the output. Usually the amount of attenuation is greater than the gain of the amplifier.

The helix-type structure is especially suitable for wide-band tubes since it is nondispersive, *i.e.*, the phase velocity does not change rapidly with frequency as illustrated in Fig. 14b. Other structures have been used in which the phase velocity is slowed
down by periodic discontinuities such as apertured disks or bends in the wave guides. These structures, being more dispersive, have a narrow frequency band and find application, because of their greater heat-dissipating ability, in very-high-power traveling-wave tubes.

18. Beam Circuit Figure of Merit. An important parameter of a microwave circuit is the ratio of the effective circuit resistance to the d-c beam resistance. For the case where the beam continuously interacts with the circuit fields (*e.g.*, for a helix) a merit factor, often called the *Pierce C factor*,[25] is defined as

$$C = \left(\frac{K}{4R_0}\right)^{1/3}$$

where R_0 is the ratio of the beam voltage and beam current and K is the effective impedance of the helix defined by Pierce as

$$K = \frac{E^2}{2\beta^2 P}$$

where E is the r-f field acting on the electron beam, β is the phase constant which is the ratio of the angular frequency ω and the average beam velocity v_0, and P is the r-f power propagating down the helix.

A figure of merit for resonant-cavity devices is

$$\gamma = \mu^2 \frac{R_0}{R}$$

where μ is the gap-coupling coefficient, R is the equivalent resistance appearing across the cavity gap due to internal cavity losses, beam loading, etc., and R_0 is the d-c beam resistance. If d is the cavity-gap spacing, the gap-coupling coefficient for gridded cavities is given by

$$\mu = \frac{\sin\left(\frac{1}{2}\omega d/v_0\right)}{\left(\frac{1}{2}\omega d/v_0\right)}$$

19. Coupling Structures. The problem of coupling the tube circuit to an external transmission line is essentially one of microwave-circuit design. Since traveling-wave tubes are usually designed to operate over a 2:1 frequency range, the design problem of obtaining a match (*e.g.*, VSWR < 1.5) is difficult, although realizable. While resonant-structure devices usually have a mechanical tuning range which is considerably smaller than for the traveling-wave tube, the matching problem is more critical since it is often affected by the presence of the electron beam (*e.g.*, the reflex klystron). In this case the matching structure is designed for proper match with the tube operating.

INTERACTION THEORY

Because of the extensive nature of microwave-tube interaction theory, only a brief outline of the principal theories can be given. They are presented here to give the engineer some idea of the theory underlying microwave-tube behavior. All interaction theories start from Maxwell's equations and the Lorentz force equation. The theories differ in detail according to the assumptions which have been made to simplify the mathematical analysis. For example, the assumption of small-signal operation permits an enormous simplification of the mathematical analysis as compared with the more general large-signal case. Other assumptions such as negligible space charge or parallel-plane tube geometry result in further simplification. While much has been accomplished, the theories developed are essentially guides in predicting the actual operation of the tube, and much work remains in this field.

20. Vacuum-tube Network Theory. A classic example of the small-signal analysis of vacuum tubes is the Llewellyn-Peterson[26] vacuum-tube network theory for a system

of parallel planes. Such a system is illustrated in Fig. 15 as an array of planes *a*, *b*, *c*, etc. Currents J_1, J_2, etc., flow in regions 1, 2, 3, etc. The analysis of such a system starts with

$$\Delta \cdot \bar{E} = \frac{\partial \bar{E}}{\partial x} = \frac{\rho}{\epsilon_0} \tag{1}$$

$$\bar{J} = \rho \bar{v} + \epsilon_0 \frac{\partial \bar{E}}{\partial t} \tag{2}$$

$$\bar{F} = m\bar{a} = -e\bar{E} \tag{3}$$

where $\bar{E}$ = electric field
$\bar{J}$ = current density
$\bar{F}$ = force on electron
$\bar{a}$ = acceleration of electron
ρ = charge density
ϵ_0 = dielectric constant of free space
x = distance measured with respect to some reference
$\bar{v}$ = velocity of the electron
t = time
e and m = charge and mass of an electron

Equations (1) and (2) can be combined to eliminate ρ so that

$$J = \epsilon_0 \left(\frac{\partial E}{\partial x} v + \frac{\partial E}{\partial t} \right) = \epsilon_0 \frac{dE}{dt} \tag{4}$$

where all vector quantities have x-directed components only. Differentiating Eq. (3) with respect to time and combining with Eq. (4) we have the important relation
$$\frac{da}{dt} = \frac{d^3x}{dt^3} = \frac{e}{m\epsilon_0} J \tag{5}$$

FIG. 15. Parallel-plane vacuum-tube system.

This equation can be solved[27] by assuming that quantities have a d-c component plus a small a-c component. For example, associated with an applied voltage consisting of a d-c component and a small a-c component are quantities such as current density, acceleration, velocity, and transit time which also have a d-c component and a small a-c component. Equation (5) is solved assuming $J = J_0 + J_1 \sin \omega t$ and the voltage required to produce this assumed current is determined after a considerable but straightforward mathematical manipulation. The result of this analysis is summarized in the Llewellyn and Peterson[26] equation:

$$\begin{aligned} V_b - V_a &= AJ + Bq_a + Cv_a \\ q_b &= DJ + Eq_a + Fv_a \\ v_b &= GJ + Hq_a + Iv_a \end{aligned} \tag{6}$$

where the coefficients A through I listed in Table 1 depend on the d-c voltages applied, the frequency, and the spacing between planes, and V = a-c voltage on the plane with respect to ground, J = a-c current density, q = a-c conduction current density, and v = a-c velocity of the electron. Subscripts a and b refer to the particular planes of the array. An inspection of Eq. (6) shows that the conditions at plane b are expressed in terms of the initial conditions at plane *a*.

Equation (6) is a remarkable set of equations in that it represents the complete solu-

tion of the small-signal case of parallel planes. From it, to cite only a few examples, can be derived the equivalent circuit of the microwave diode, triode, tetrode, two- and three-cavity klystrons, etc.[26,27,28]

21. Ballistic Theory. Many microwave tubes are operated at high beam voltages and low current densities. In these cases, the space-charge term of Eq. (1) can be neglected entirely, and one need consider only the conduction-current term in Eq. (2). This is equivalent to assuming the electron to be a simple charged mass whose motion is dependent only on the electric and magnetic fields. There results a considerable simplification of the analysis and in some cases, as for the klystron tube, a quasi large-signal theory can be developed.[12,13,28,29]

Table 1. Vacuum-tube Network Coefficients

$$A = \frac{1}{\epsilon_0}(u_a + u_b)\frac{T^2}{2}\frac{1}{\beta}\left[1 - \frac{\zeta}{3}\left(1 - \frac{12S}{\beta^3}\right)\right]$$

$$B = \frac{1}{\epsilon_0}\frac{T^2}{\beta^3}[u_a(P - \beta Q) - u_b P + \zeta(u_a + u_b)P]$$

$$C = -\frac{1}{\eta}2\zeta(u_a + u_b)\frac{P}{\beta^2}$$

$$D = 2\zeta\left(\frac{u_a + u_b}{u_b}\right)\frac{P}{\beta^2}$$

$$E = \frac{1}{u_b}[u_b - \zeta(u_a + u_b)]e^{-\beta}$$

$$F = \frac{\epsilon_0}{\eta}\frac{2\zeta}{T^2}\left(\frac{u_a + u_b}{u_b}\right)\beta e^{-\beta}$$

$$G = \frac{-\eta}{\epsilon_0}\frac{T^2}{\beta^3}\frac{1}{u_b}[u_b(P - \beta Q) - u_a P + \zeta(u_a + u_b)P]$$

$$H = -\frac{\eta}{\epsilon_0}\frac{T^2}{2}\left(\frac{u_a + u_b}{u_b}\right)(1 - \zeta)\frac{e^{-\beta}}{\beta}$$

$$I = \frac{1}{u_b}[u_a - \zeta(u_a + u_b)]e^{-\beta}$$

where $P = 1 - (1 + \beta)e^{-\beta} \doteq \beta^2/2 - \beta^3/3 + \beta^4/8 + \cdots$
$Q = 1 - e^{-\beta} \doteq \beta - \beta^2/2 + \beta^3/6 - \beta^4/24 + \cdots$
$S = 2 - \beta - (2 + \beta)e^{-\beta} \doteq -\beta^3/6 + \beta^4/12 - \beta^5/40 + \beta^6/180 + \cdots$
$\beta = j\theta = j\omega T$

D-c Equations

Limiting current density:

$$J_m = 2.33 \times 10^{-6}\frac{[(V_{D_a})^{1/2} + (V_{D_b})^{1/2}]^3}{d^2}$$

Definition of space-charge factor ζ:

$$\frac{J_0}{J_m} = \frac{9}{4}\zeta\left(1 - \frac{\zeta}{3}\right)^2$$

Transit time:

$$T = \frac{T_0}{1 - \zeta/3}$$

where $T_0 = \dfrac{2d}{u_a + u_b}$ = transit time in absence of space charge

D-c velocity:

$$u = (2\eta V_D)^{1/2}$$

Distance equation:

$$x = \left(1 - \frac{\zeta}{3}\right)(u_a + u_b)\frac{T}{2}$$

where $\eta = e/m = 1.76 \times 10^{11}$ coulombs/kg
J_0 = density of d.c.
$\epsilon = 1/(36\pi \times 10^9)$ farads/m
V_D = d-c potential
$\eta/\epsilon = 2 \times 10^{22}$

As an illustration of this theory assume Fig. 15 to be a schematic representation of a klystron in which planes a, b and c, d are closely spaced cavity grids separated by the relatively long field-free drift region (2). If a small a-c signal is applied to the first gap, an integration of Eq. (3) will show that the velocity of the electrons leaving the gap is modulated and given by

$$v = v_0 \left(1 + \frac{\mu\alpha}{2} \sin \omega t\right) \tag{7}$$

where v_0 is the velocity of the unmodulated beam and α is the ratio of the peak a-c voltage to the d-c beam voltage, μ is the gap-coupling coefficient previously defined, and ω is the angular frequency of the gap voltage. These electrons are injected into the field-free drift region and the arrival time t_2 of a particular electron at the second cavity gap is dependent on its instantaneous velocity when it left the cavity. If L is the length of the drift space and t_1 is the value of the electron departure time, then for small values of $\frac{1}{2}\mu\alpha$,

$$t_2 = t_1 + \frac{L}{v} \approx t_1 + t_0 \left(1 - \frac{\mu\alpha}{2} \sin \omega t_1\right) \tag{8}$$

where $t_0 = L/v_0$. Since $\theta = \omega t$, this can be written in terms of transit angles as

$$\theta_2 = \theta_1 + \theta_0 - x \sin \theta_1 \tag{9}$$

where $x = \frac{1}{2}\mu\alpha\,\theta_0$, the bunching parameter.

The next important step in the ballistic theory is the application of the continuity-of-charge equation. This states that the total charge arriving at the second cavity gap in the time interval dt_2 consists of the sum of all the charges leaving the first cavity gap in the corresponding intervals dt_1. This is equivalent to

$$I_2\, dt_2 = \Sigma I_1\, dt_1 \tag{10}$$

where I_1 is the d-c beam current at the first gap and I_2 is the beam current at the second gap. From Eq. (8) we have

$$\frac{dt_2}{dt_1} = 1 - x \cos \omega t \tag{11}$$

which shows that for a particular dt_2 there are either one or three corresponding values of dt_1. Thus

$$\frac{I_2}{I_1} = \sum \frac{1}{|1 - x \cos \theta_1|} \tag{12}$$
FIG. 16. Plot of I_2/I_1 vs. $(\theta_2 - \theta_0)$.

If various values of θ_2 are assumed, the corresponding values of θ_1 can be calculated from Eq. (9) and substituted in Eq. (12) to obtain I_2. A plot of I_2/I_1 vs. $(\theta_2 - \theta_0)$ for one cycle is shown in Fig. 16. If a Fourier analysis of this curve is taken,[12,13,28,29] the current at the second gap is

$$I_2 = I_1 \left[1 + 2J_n(nx) \sin (n\omega t)\right] \tag{13}$$

where I_1 is the d-c term and n is the harmonic frequency considered. The fraction of this current actually induced in the cavity gap is μ, so that, if the shunt resistance R_{sh} of the second cavity is known, the peak value of the a-c cavity-gap voltage can be calculated as $2I_1J_n(nx)\mu R_{sh}$ and hence the transconductance, voltage gain, etc., can be calculated. These results are identical to those predicted using the vacuum-tube network equations except for the $2J_n(nx)$ term. In a similar fashion, other tube types can be analyzed if the simplifying assumptions made apply.

22. Linear-beam Theory. Clearly the advantage of the vacuum-tube network theory for parallel planes is that it describes completely the small-signal characteristics of a large number of tubes. For tubes having linear beams, *i.e.*, in which the electron beam has a predominantly large velocity component in a particular direction, a similar unified theory has been proposed by Wang.[30] To achieve different interaction functions, various r-f structures are usually built around the beam such as a helix or cavity arrays. Instead of considering a special theory as each tube is developed, a general one is developed which permits a solution of specific tubes with the least amount of modification. It is possible then, with the aid of electronic-computer devices, to determine the characteristics of a wide variety of structures in a relatively short time.

In special cases, closed-form solutions can be obtained, and as an illustration, Pierce's analysis[25] of the traveling-wave tube will be reviewed briefly. In his simplified analysis, a circuit is assumed (*e.g.*, a helix) which has one active mode with a phase velocity near the electron speed. It is further assumed that all a-c quantities vary as exp $(j\omega t + \Gamma z)$, where Γ is the propagation constant $\alpha + j\beta$ of the active
FIG. 17. Equivalent circuit of the traveling-wave tube.

circuit and z is the distance along the length of the tube. In the simple case of lossless circuit $\Gamma = \Gamma_0 = j\beta$ with no beam, where $\beta = \omega/u_0$, the phase constant of the slow wave. If we know β and the effective impedance K of the circuit[25] previously defined, an equivalent distributed active circuit can be drawn having a series reactance X and shunt susceptance B related to β and K according to

$$K = \sqrt{\frac{X}{B}} \tag{14}$$

$$\Gamma_0 = j\beta = j\sqrt{XB} \tag{15}$$

The presence of a beam traveling with approximately the same velocity as the wave is assumed not to change X and B but, because of the bunching in the beam, impresses a current per unit length J on the equivalent circuit. The telegrapher's equations therefore take the form

$$\frac{\partial I}{\partial z} = -jBV + J \tag{16}$$

$$\frac{\partial V}{\partial z} = -jXI \tag{17}$$

where I and V are the equivalent current and voltage on the circuit. If i is the a-c conduction current in the beam, the equivalent circuit in the beam is as shown schematically in Fig. 17. Since all a-c quantities vary as exp $(j\omega t + \Gamma z)$, the solution of

V in terms of i is

$$V = -j \frac{\Gamma\Gamma_0}{\Gamma^2 - \Gamma_0^2} i \tag{18}$$

which gives the voltage (or electric field) on the equivalent circuit in terms of an assumed impressed current i.

Pierce[25] next calculates the conduction current in the beam produced by an assumed voltage V. Since conduction current is the product of the electron velocity and space-charge density, the a-c conduction current is approximately

$$i = \rho_0 v + v_0 \rho \tag{19}$$

where the product of the a-c terms has been neglected for the small-signal case. In Eq. (19) the quantities with the subscripts refer to the d-c components. By a simple application of Newton's force equation and the equation of the conservation of charge v and ρ can be expressed in terms of V. From the force equation

$$\frac{dv}{dt} = \frac{\partial v}{\partial t} + \frac{\partial v}{\partial z} v = \frac{e}{m} \frac{\partial V}{\partial z} \tag{20}$$

or, since exponential solutions are assumed,

$$v = -\frac{e/m\Gamma}{v_0(j\beta - \Gamma)} V \tag{21}$$

From the equation of conservation of charge

$$\nabla \cdot i = \frac{\partial i}{\partial z} = \frac{-\partial \rho}{\partial t} \tag{22}$$

or

$$\rho = -j \frac{\Gamma i}{\omega} \tag{23}$$

Equations (21), (23), and (19) are then arranged as

$$i = j \frac{I_0}{V_0} \frac{\beta\Gamma}{(j\beta - \Gamma)^2} V \tag{24}$$

where I_0 and V_0 are the d-c beam current and voltage.

The final step is to find the values of Γ which satisfy both Eqs. (18) and (24). This is done by equating the two and solving for Γ. To simplify the analysis it is assumed Γ is only slightly affected by the presence of the beam so that

$$-\Gamma = -\Gamma_0 + \zeta \tag{25}$$

where $|\Gamma_0| \gg |\zeta|$. Carrying out the solution the propagation constants are

$$\Gamma_1 = \beta \left[-\frac{\sqrt{3}}{2} C + j\left(1 + \frac{C}{2}\right) \right] \tag{26}$$

$$\Gamma_2 = \beta \left[\frac{3}{2} C + j\left(1 + \frac{C}{2}\right) \right] \tag{27}$$

$$\Gamma_3 = j\beta(1 - C) \tag{28}$$

These are three forward waves. A similar analysis will show a fourth propagation constant of a wave whose direction of propagation is opposite to the direction of the

beam:

$$\Gamma_4 = -j\beta\left(1 - \frac{C^3}{4}\right) \tag{29}$$

Equation (26) shows that one of the three forward waves has a negative attenuation constant. Since the waves vary as exp $(-\Gamma_z)$, the voltage gain of the growing wave of a tube expressed in decibels is $47.3CN$, where C is the merit factor previously defined and N is the length of the tube expressed in wavelengths. The amplitudes of the three forward waves at the input are equal to one-third the impressed signal voltage[25] so that the over-all gain of the tube is

$$\text{Voltage gain (db)} = -9.54 + 47.3CN \tag{30}$$

PRINCIPAL MICROWAVE TUBES

Microwave tubes are used mainly in the 1- to 100-kilomegacycle frequency range. To cover this range a wide variety of tubes have been developed, each with its particular advantage and limitation. The choice of a tube for a particular application will include such considerations as tube efficiency, gain, noise, sensitivity to load, and other electrical characteristics; tube mechanical characteristics such as size, weight, and

resistance to shock and vibration; and economic factors such as cost and availability. Because of the rapidly changing technical development of microwave tubes, it is not possible to catalogue these considerations at present, and this discussion is limited to the general features of the more important types. A few of the principal types of microwave tubes will be discussed.*

23. Microwave Triodes. Microwave triodes operate satisfactorily at frequencies up to about 4,000 Mc, at which the available output power drops to a few milliwatts

NOTES: (I) The parameters listed in this table for a specific tube type obviously cannot all be gotten simultaneously with one tube. The figures represent the best or near-best that has been attained so far with tubes in a particular class. (II) Noise figures for "wave"-type amplifiers are for low-noise tubes. These are all limited in power-handling ability. (III) "Wave" tubes have the remarkable property of being relatively insensitive to load changes.

for c-w operation, or a few watts peak for pulsed operation. The chief limitation in modern microwave triodes is the long transit time of electrons in the grid-cathode space. The engineering approach to overcome this has been to design tubes with close interelectrode spacing and with a high equivalent grid-plate voltage. The factors which determine the ultimate limitation are the maximum available cathode current density, the small physical size of the structure required, and the maximum allowable tube-element temperature.

Fig. 18. Microwave triode structure.

Recent improvements in the high-frequency performance of triodes have resulted from an improvement in materials and techniques. For example, Fig. 18 shows the design of an experimental tube capable of operation up to 10 kilomegacycles. The use of ceramics and high-temperature getters permits this tube to be operated at high bulb temperatures so that the dissipation ratings can be increased. Further improvements in triodes can be expected when the current-density capabilities of cathodes are increased.

Because of the high operating efficiency and low noise characteristics of triodes at the lower end of the microwave band and because their cost is low compared with other tubes, the microwave triode is a particularly important member of the microwave-tube family.

24. Klystron Tubes. In contrast with microwave triodes, klystron tubes are dependent on transit-time effects for efficient operation. As discussed previously, a cavity resonator is used so that a small amount of drive power will cause a high a-c voltage to appear across the cavity gap. The resulting velocity modulation and bunching action produce a large a-c current in the beam. A second tuned cavity (Fig. 19*b*) is located a suitable distance from the first and a high voltage is induced across the catcher grids. Useful power is coupled out of the cavity by means of some coupling device, such as the loop illustrated, and is delivered to a load terminating the transmission line.

Increased amplifier efficiency results when one or more tuned cavities are placed between the input and output cavities. Figure 6 shows a three-cavity cascade klystron. The highest plate efficiency of these tubes is of the order of 30 to 45 per cent. Most klystrons are ½ to 20 per cent efficient. Their chief advantages are that the structures are able to dissipate large amounts of heat, and the cavities provide good frequency stability. Output powers range from a few milliwatts for low-voltage amplifiers to as high as 30 megawatts peak pulse power.[31]

Since the klystron bunching action produces large amplitude harmonics, if the second cavity is tuned to a higher harmonic, the klystron can be used as a frequency multiplier. Clearly, of course, the beam must be redesigned to ensure adequate transmission of the beam through the smaller cavity. Multiplication ratios of 10 to 20 are typically used.

If, as illustrated in Fig. 19*b*, a reflector turns the beam back upon itself, the cavity resonator acts as both the buncher and the catcher. The phase of the returning beam can be adjusted so that energy is extracted from the beam and delivered to the a-c field to produce oscillations. Small changes in the reflector voltage will result in a change in the phase between the a-c current in the beam and the a-c gap voltage. Thus, with some sacrifice in power, the oscillation frequency can be shifted slightly. A typical power and frequency characteristic of a reflex klystron is shown in Fig. 20.

Although the efficiency of the reflex klystron is of the order of only 0.1 to 10 per cent, its simple structure and ease of mechanical and electronic tuning make it a very useful signal source.

25. Traveling-wave Amplifiers. The traveling-wave amplifier is similar in many respects to the klystron. The velocity modulation occurring in the klystrons also occurs in the traveling-wave tube but in a more gradual manner since the impedance of the circuit is low. However, the interaction occurs over a longer distance so that the net effect is about the same in the two tubes. The electrons traveling down the tube axis are grouped so that the a-c field of the circuit slows down the bunched electrons, thereby transforming some of the kinetic energy of the electrons into useful r-f energy. The electron velocity should be slightly greater than the phase velocity of the wave propagation down the slow-wave structure. Fortunately, for many slow-wave structures the phase-velocity variation as a function of frequency is very slight; therefore high gain is possible over a frequency range of about an octave or more without any adjustment of the beam voltage or circuit.

Output powers of the order of milliwatts to kilowatts are attainable for continuous operation, megawatts are attainable for pulse operation, and noise figures as low as 6.5 db have been attainable over a relatively broad frequency range, which makes them useful as r-f amplifiers for receivers. New developments in traveling-wave tubes include light-weight tubes that are focused electrostatically or by means of periodic magnets.

(*a*)

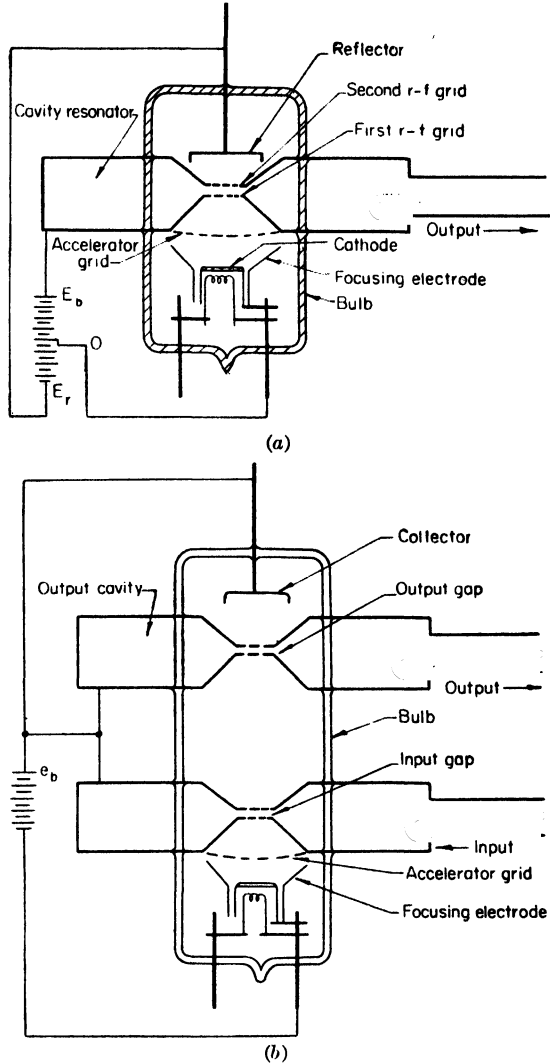
(*b*)


FIG. 19. (*a*) Schematic drawing of reflex klystron in glass bulb with resonant cavity, loop, and line attached. The space between the first and second r-f grids is the ***interaction gap***. Electrons become bunched in the ***drift space*** located between the interaction gap and the reflector. (*b*) Schematic drawing of two-cavity klystron. Bunching action is begun in the input gap. In the output gap the bunching of the electrons reaches an optimum value. This type of tube may be used for amplification at microwave frequencies or for frequency multiplication.

The traveling-wave tube is one of the most important amplifiers of the microwave-tube family because of its very wide band width, low noise, high power, and high gain. Its chief drawback is its relatively low efficiency. At high power levels, 20 to 25 per cent efficiencies are attainable, and at low power levels the efficiency drops to a few per cent

26. Backward-wave Tube.[32] The backward-wave tube is a device which can operate as a voltage-tunable oscillator or amplifier over a wide frequency range.
FIG. 20. Power output and electronic tuning of a reflex klystron.

Satisfactory operation over as high as a 3:1 frequency range and continuous output powers ranging from milliwatts to kilowatts have been obtained.

A periodic-type interaction structure, such as the helix, is used, but the circuit is designed to operate in the highly dispersive region where the group velocity is opposite to the phase velocity. For proper operation the phase velocity as a function of frequency should vary rapidly with frequency in the manner indicated in Fig. 14*b*.

A schematic diagram of the backward-wave tube is shown in Fig. 21. The r-f field of the backward-wave circuit has a phase velocity slightly less than the beam, and energy is transferred from the beam to the field in a manner similar to that occurring in the traveling-wave amplifier. The r-f energy flow on the circuit in this case is in a direction opposite to the phase velocity and is fed back to the input. For positive feedback the total phase shift around the loop must be an integral number of cycles. In terms of the phase velocity v_p, the average velocity of the electrons in the beam v_0, the angular frequency ω, and the length of the tube L, the condition for phase reinforcement is
FIG. 21. Schematic circuit of a backward-wave tube.

$$\omega = \frac{(2n + 1)\pi}{[(1/v_p) - (1/v_0)]L}$$

where n is usually equal to zero. Since v_p depends on ω it is clear that ω is dependent on v_0. Since v_0, in turn, depends on the beam voltage, the device is therefore voltage-tunable.

If a signal is fed into the circuit at the right-hand end of the tube and if the tube is voltage-tuned to the frequency of the signal, the signal appearing at the left end of the tube will be amplified. For operation as an amplifier there must, of course, be enough

feedback to produce a net gain greater than unity but not so much as to produce oscillations. The effective Q of this amplifier is exceptionally high, permitting operation in the millimeter-wavelength bands. If the beam current is made relatively large, the loop gain becomes infinite and the tube becomes a voltage-tunable oscillator.

In addition to the important advantage of voltage tuning, the backward-wave oscillator, since it has no resonant circuit, is entirely immune from frequency pulling by the circuit. Frequency modulation can be obtained by varying the beam voltage and amplitude modulation can be obtained by varying the beam current.

27. Microwave Magnetron Oscillator.[13,23,24,28,29,33] The magnetron is one of the most important members of the microwave-tube family. Magnetrons are used extensively as sources of c-w power and high-pulse power. For pulse operation they are capable of delivering megawatts of peak powers in the lower-frequency ranges and milliwatts of power in the millimeter range. Pulse operation is accomplished by anode modulation with rectangular pulses of 0.5 to 10 μsec duration. For c-w operation, kilowatt power levels are readily obtainable at lower portions of the microwave frequency range. Load efficiencies as high as 70 per cent have been obtained.

FIG. 22. Paths of electrons in simple magnetron; *a*—electrons giving energy to the r-f field, *b*—electrons in absence of r-f field, *c*—electrons extracting energy from the r-f field.

The circuit of the microwave magnetron is similar to that illustrated in Fig. 13*b*. Two waves exist traveling in opposite directions. If a positive voltage is applied to the anode and a magnetic field normal to the electric field is applied, the electrons will rotate around the cathode with an average velocity approximately equal to the
FIG. 23. Paths followed by unfavorable and favorable electrons in a magnetron.

ratio of the electric and magnetic fields. If this velocity is slightly greater than the phase velocity of one of the two waves, interaction will occur in a manner similar to that for the traveling-wave tube. An important difference, as illustrated in Fig. 22, exists for the magnetron which results in high electronic efficiency. Electrons which tend to absorb energy from the r-f field, and therefore are unfavorable electrons, are quickly returned to the cathode. On the other hand, the favorable electrons which contribute potential energy to the r-f field remain in the interaction space for a rela-

tively long time, finally striking the anode but with low kinetic energy. This electron-sorting mechanism results in the very high efficiency of the magnetron.

Figure 23 shows the path followed by an unfavorable (A) and a favorable (B) electron in an actual oscillating magnetron. Since the unfavorable electrons are returned, the resultant space charge appears as "spokes of a wheel" rotating at approximately the phase velocity of the circuit wave, as illustrated in Fig. 24. Since the magnetron operates using a highly resonant circuit, a reactive load will pull the frequency of oscillation.
Fig. 24. Rotating space charge in magnetron.

While the magnetron is the most widely used microwave tube, free-running oscillators are losing popularity in many microwave systems. Short life has been a problem on some types, and the narrow range of mechanical tuning is a drawback. Considerable effort is being exerted to overcome these deficiencies. Notable among the new developments is the voltage-tunable magnetron (VTM) having characteristics highly competitive with the backward oscillator.[33]

28. M-type Tubes.[34] A schematic diagram of the M-type tube is shown in Fig. 11. In many respects this tube is similar to the traveling-wave, backward-wave, and magnetron tubes discussed. As with the two former types a slow-wave interaction structure is used, having the group and phase velocities in the same or opposite direction depending on the type of operation desired. A crossed E and H field is employed, as in the magnetron, to remove unfavorable electrons from strong interaction regions. An important additional advantage of this structure is that the cathode is separate from the interaction space and is not subject to the deleterious effects of back bombardment of electrons. As with the magnetron, the paths of the electrons are similar to those shown in Fig. 22. The kinetic energies of the three groups of electrons are approximately equal. The electrons following path a are contributing energy to the r-f field, but as for the magnetron this is a conversion of d-c potential energy into r-f energy. This energy exchange is in contrast with the klystron and traveling-wave tubes where the d-c kinetic energy of the electrons is converted into r-f energy.

Tubes operating as forward-wave amplifiers are often referred to as M-FWA, or as TPOM (*tube à propagation d'onde*). Efficiencies of 50 per cent are obtainable for tubes operating with band widths of 25 per cent and gains of approximately 30 db. New developments in this field include a coaxial-type structure, the center conductor of which carries a direct current to provide concentric lines of magnetic flux.

The backward-wave oscillators are referred to as M-BWO or as M-carcinotrons. These tubes have high efficiency, high power, and are voltage tunable. Their chief limitation, at present, appears to be noise. Very little work seems to have been done on the backward-wave amplifier (M-BWA).

29. New Microwave Tubes. The types of microwave tubes discussed so far have been applied very successfully in a wide variety of microwave systems. There is, of course, a constant demand for improved tube performance which results in an increasing number of new basic types of tubes. The most notable of the newer tubes in recent years have been of the crossed-field type, a few of which are discussed below.

Crossed-field types (also called M-types*) are tubes in which the electron beam flows normal to mutually perpendicular d-c magnetic and electric fields. The magnetron is an older member of this group. The newer types which are discussed include the

* See Glossary of Important Microwave-tube Terminology on page 8-26.

M-type forward-wave amplifiers, backward-wave amplifiers, and oscillators, the amplitron, and the Stabilitron.

30. Platinotron.[38] The Platinotron* is a crossed-field tube which can be used as an amplifier or as an oscillator. The tube, shown schematically in Fig. 25, is very similar to the magnetron but has two external connections, one for the input and one for the output. As shown in Fig. 25, the "spokes" of the beam travel in a direction opposite to the wave. The tube is essentially a backward-wave amplifier with electronic regenerative feedback.

FIG. 25. Mode of operation of a Platinotron is complex, utilizing crossed electric and magnetic fields and a reentrant slipping-stream electron beam to give backward-wave behavior. (*Electronics, August,* 1957, *p.* 164.)

When used as an amplifier the tube is referred to as an Amplitron.* In this case, power is fed to the input, and amplifier power is obtained from the output terminal. Efficiencies of 50 to 75 per cent are obtainable at approximately 10-db gain and 10 per cent band width. It is possible to operate the tube with pulse widths up to 20 μsec in duration.

When the tube is used as a self-excited stabilized oscillator, it is called the Stabilitron. Figure 26 is a schematic circuit of the device. Self-excitation results from the feedback from the mismatch in the output circuit and the reflection from the resonant circuit. The wave reflected to the left reaches the resonant circuit with no appreciable change in amplitude but with some phase shift. The wave reflected to the right is amplified by the tube and also experiences phase shift. By proper adjustment of the reflection coefficients and the phase shift around the loop, the tube can be made to oscillate. The use of a high-Q circuit allows for considerable stabilization. Tuning is accomplished by changing the resonant frequency of the stabilizing cavity. Over-all efficiencies of 45 to 60 per cent are obtainable.

FIG. 26. The Stabilitron.

Glossary of Important Microwave-tube Terminology.[12, 23, 35, 36] The terms of the previous sections apply in addition to the following:

Admittance. The ratio of the a-c current flowing into the input terminals to the a-c voltage appearing across the input terminals. The circuit input admittance is the portion of the input admittance due to the circuit alone, and the electronic input admittance is the portion of the input admittance due to the electron beam alone.

Transadmittance. The ratio of the a.c. flowing from the tube output terminals to the a-c voltage appearing across the input terminals.
FIG. 27. Performance chart (of a magnetron).

Pulsed Frequency Spectrum and Band Width. The frequency spectrum of a pulsed oscillator is a plot of the r-f energy distribution vs. the frequency of oscillation.

The frequency-spectrum band width is the frequency interval between two points of equal power (usually the quarter-power points) on the frequency spectrum.

Efficiency. Electronic efficiency. The ratio of the total r-f power generated to the d-c power in the electron beam.

Circuit efficiency. The ratio of the r-f power delivered to the load to the total r-f power generated.

Load efficiency. The ratio of the r-f power delivered to the load to the d-c power in the electron beam. Also, it is the product of electronic efficiency and circuit efficiency.

Frequency Pulling and Pushing. Frequency pulling is the change in frequency of oscillation caused by a change in load admittance. The *pulling figure* of an oscillator is the maximum change in frequency which occurs when the phase angle of the load

(usually adjusted to have a VSWR of 1.5) is varied through at least one-half of a guided wavelength.

Frequency pushing is the change in frequency of oscillation due to a change in anode current. The *pushing figure* of an oscillator is the maximum change in frequency which occurs when the anode current is changed a certain amount (not including frequency changes due to thermal effects).

Gain. The ratio of the output power to the input power. For small input signals, the gain is referred to as the small-signal gain. At large signals the gain is often compressed and the gain is referred to as the large-signal gain.
FIG. 28. Rieke diagram (of a reflex oscillator).

M-type Tubes. Wave-type tubes in which the electron beam flows normal to mutually perpendicular d-c magnetic fields. These tubes are also called *crossed-field tubes.*

Noise and Spurious Responses. The noise figure is the ratio of the available signal-to-noise ratio at the amplifier input terminals to that available at the output terminals.

The signal-to-noise ratio of an oscillator is the ratio of the r-f power generated at the oscillator frequency to the noise power contained within a specified frequency band or bands.

Spurious responses are miscellaneous unwanted signals appearing in microwave amplifiers and oscillators because of various causes such as ion phenomena in the beam, coupling between undesired circuit harmonics and beam harmonics, microphonics, heater hum, and leakage.

O-type Tube. Wave-type tubes in which the electron beam flows parallel to the magnetic field (O-type refers to ordinary-type tubes).

Performance Chart. A plot of anode voltage vs. anode current for constant values of magnetic field, constant output power, and constant load efficiency (see Fig. 27).

Q. The Q of a resonant circuit for a microwave tube is defined as 2π times the ratio of the electromagnetic energy stored per cycle to the energy lost per cycle at the resonant frequency.

The *loaded Q* of a resonant circuit is 2π times the ratio of the electromagnetic energy stored per cycle to the energy lost per cycle in the internal losses and the coupled-in external load. The *unloaded Q* is the value one would obtain if the energy were lost in the internal losses only. The *external Q* is the value one would obtain if the energy were lost in the coupled-in external load only. These definitions give rise to the relationship

$$\frac{1}{Q_{\text{loaded}}} = \frac{1}{Q_{\text{unloaded}}} + \frac{1}{Q_{\text{external}}}$$

Rieke Diagram. A chart showing the loci of load admittances giving constant power and constant frequency. The chart is often plotted on a Smith chart (see Fig. 28).

Tuning. The *tuning range* is the frequency interval over which the tube is considered operable. The *mechanical tuning range* is the frequency interval over which it can be mechanically tuned, and the *thermal tuning range* and *electronic tuning range* are the intervals over which the tube can be tuned by thermal or electronic means.

CHAPTER 9

SEMICONDUCTOR DIODES

BY W. F. PALMER[1]

1. General. These two-element electron devices are available in a wide variety of forms. All depend upon a contact or junction between two suitable dissimilar metals
FIG. 1. Volt-ampere characteristics of a semiconductor power-rectifier diode. (*a*) Equal scales. (*b*) Expanded scale.

or certain other compounds (as metallic oxides). A potential barrier which appears at this junction or interface is responsible for the nonlinear or nonohmic volt-ampere conduction characteristic which results. It is this nonlinear characteristic which

[1] Sylvania Electric Products Inc.

makes possible the use of these devices as rectifiers or detectors. Figure 1 illustrates the nonohmic response of a semiconductor rectifier. Note the nearly ideal diode characteristic. Semiconductor diodes are made from a wide variety of materials or compounds and in various sizes ranging from subminiature types to large rugged power rectifiers. They may be used to detect minute r-f signals or to rectify kilowatts
FIG. 2. Various semiconductor constructions.

of low-frequency a-c power. Figure 2 shows typical construction of several types of diodes.

Various classes of diodes and their major characteristics are given in Table 1.

2. Historical Note. The earliest common use of a semiconductor detector was that of crystalline lead sulfide (galena) in early radio reception. Later, copper-sulfide and copper-oxide devices were used as rectifiers and photocells. In the 1930's, research into semiconductor theory led to the development of metallic rectifiers, selenium being

the first of commercial importance, followed by silicon and germanium point-contact diodes in the 1940's and later by the large-area silicon and germanium types which are becoming commercially available at present.

Table 1. Various Types of Semiconductor Diodes

Construction	Material	Power	Frequency	Application notes
Point contact	1. Germanium	Low to medium	To 250 Mc, higher in appropriate designs	Detection, frequency conversion, etc.; clippers; clamps; rectifiers within ratings
	2. Plated whisker or "bonded"	Low to medium	To 250 Mc, higher in appropriate designs	Higher forward conduction than (1), applications similar to (1)
	3. Silicon	Low to medium	To 500 Mc	Applications as for (1) but may have exceptionally low recovery time
	4. Silicon microwave	Low to medium	To many 1,000 Mc in appropriate designs	Radar detectors, mixer, etc.
	5. Selenium*	Low to high	To 10 Mc or more in appropriate designs	Primarily as a rectifier
Junction	6. Germanium	Low to high	To 10 Mc or more in appropriate designs	As in (1) above, longer recovery time than point-contact types, power rectifiers
	7. Silicon	Low to high	To 10 Mc or more in appropriate designs	As for (6) above, sharp reverse breakdown or saturation voltage permits use as regulator

* Has been classified as a junction but may be considered as a large-area contact type.

3. Materials. Materials from which semiconductor diodes are commonly made are listed below. Many others of less commercial significance are not included:

1. Selenium—widely used in power rectifiers and photocells
2. Germanium—becoming commonly used in a wide range of diodes
3. Silicon—becoming commonly used in a wide range of diodes
4. Copper sulfide—not widely used at present
5. Intermetallic compounds—experimental only at present but potentially useful in future types
6. Cadmium sulfide—primarily used in highly sensitive photocells

DIODE APPLICATIONS

Applications of semiconductor diodes may be classified as detectors, rectifiers, switches, and logic elements in bistable circuits. They may also be used as variable impedances.

4. Detectors. These are diodes used for the detection of alternating signal currents—usually at relatively low power levels and relatively high frequencies. Detection is nonetheless rectification of an alternating current, but this term is usually reserved for applications in which information in one form or another is carried by the signal. Typical use of point-contact diodes in amplitude-modulation detectors is shown in Fig. 3.

5. Detection Efficiency. Detection efficiency varies considerably with the applied signal voltage, as does linearity. In general, both are improved as signal level is increased. At relatively high levels the forward current produces a negligible voltage drop across the diode, but this drop becomes significant at lower levels. At very low levels, the diode does not conduct to any great extent and the nonlinearity of its transfer characteristic is not pronounced, so that rectification efficiency is very low, and the diode is a poor detector.

Figure 4*a* shows the calibration curve of a typical germanium point-contact diode used as an r-f detector. In the region between zero and approximately 0.25 volt, the output voltage is proportional to the square of the input, but it becomes linear at higher input voltages.

FIG. 3. Typical a-m detectors.

Detection efficiency also varies with frequency but is nearly constant to several hundred megacycles for point-contact types (see Table 1). Figure 4*b* shows a typical frequency-response curve for a germanium point-contact diode. That of certain silicon types may be somewhat better.

With suitable attenuators and amplifiers, semiconductor diode detectors may be useful over a wide range of input voltages (1 mv or less upward) and frequencies (zero to thousands of megacycles).

FIG. 4. (*a*) Germanium-diode rectification curve. (*b*) Detector output vs. frequency.

6. Rectifiers. These are diodes which are used to convert a-c power to d-c power for operation of equipment which cannot be operated from the former. (For example, d.c. is usually required for operation of tube or transistor amplifiers, electrolytic refining of certain metals, d-c motors, etc.) Rectification of lower-frequency power at relatively high levels is most common. During one half cycle of the applied a-c voltage, polarity is such as to bias the diode "on," and current flows in the diode-load circuit. During the other half cycle the diode is biased "off" and essentially no current flows in the load. Where the ripple component may not be tolerated, rectification is commonly followed by suitable filters. The high rectification efficiency and lack of heated cathodes are important advantages over thermionic rectifiers.

7. Rectification Ratio. The rectification ratio of a diode is the ratio of its d-c reverse resistance to its d-c forward resistance at arbitrarily specified voltages. These voltages are usually chosen to be representative of peak or average voltages encountered in a particular application or class of applications. If these points are wisely chosen, the rectification ratio gives a fair indication of the rectification efficiency likely to be obtained in actual application. A high rectification ratio is desirable and indi-

FIG. 5. D-c restorer.

cates highly efficient rectification or detection at the particular current and voltage levels.

Rectification ratios at low voltages and high currents may not accurately indicate the actual efficiency of rectification (Sec. 5), however, as the diode forward voltage may be a significant fraction of the peak input voltage. Under these conditions, germanium or selenium diodes may be more efficient than silicon types even though the latter have high rectification ratios. Figure 6 illustrates this point.

8. Limiting of Peak Currents in Rectifiers. When rectifiers are operated with a capacitive load, surge and peak currents may be greater than the diode ratings. The insertion of an impedance in series with the diode will often permit use of the diode by increasing the conduction angle and lowering the peak and surge current to safe values without seriously reducing output rectified power. Where resistive losses may be excessive, a series inductor will be useful and essentially becomes the filter input choke.

Since calculation of peak and surge currents is tedious, requiring knowledge of a great many circuit parameters, an experimental method of testing and modifying the circuit during design is given in Fig. 7. Diode current is sensed by R_1 and displayed on the calibrated oscilloscope. Placing the resistor in the common or ground lead will permit grounding the oscilloscope. Where a differential oscilloscope is available, the resistor may be placed directly at the diode terminals, also permitting the oscilloscope to be grounded. R_1 may also function as the limiting resistor or as a separate low-resistance shunt.

Diode voltage may also be observed if the diode is placed near ground potential or if the oscilloscope is floated. (Observe suitable precautions if high voltages are involved.)

FIG. 6. Diode rectification with resistive load.

Instantaneous dissipation can also be observed if voltage and current are displayed on the different oscilloscope axes. Dissipation hyperbolas may be drawn on the display screen to facilitate reading. Note that the isolating network R_2d_2 is needed to remove inverse voltage across the diode when this is sufficient to damage the oscilloscope or affect its accuracy of voltage readings. R_2, of course, must be considered as an input attenuator

FIG. 7. Rectifier current and dissipation test circuits. (*a* and *b*) Oscilloscope grounded; (*c* and *e*) oscilloscope floating; (*d*) transformer secondary grounded.
FIG. 8. Typical ring or bridge modulator.

to the oscilloscope, and calibration should be made with the network in place. Diode d_2 is a scale switch which protects the oscilloscope from diode inverse voltage without affecting its reading of forward rectifier voltage, and its "off" resistance should be much greater than R_2. A small-area silicon-junction type will be suitable.

9. Switches. Diodes used in a variety of nonrectifying applications may be termed switches, though it is perfectly correct to consider both rectifiers and detectors as switching applications of diodes.

When reverse-biased band conduction is very low, the diode is said to be in the "off" condition, and, conversely, when forward-biased into a high-conduction region it is said to be "on." Thus, the analogy with a mechanical switch is good. Unlike a mechanical switch, relay, vacuum tube, or transistor, no isolated input is available for control purposes, and the diode can be switched from state to state only by reversal of the potential across its terminals. This ability to become a near short circuit when forward-biased leads to the use of suitable diode types in clipping, clamping, chopping, d-c level restoring, and a host of similar applications. Figures 5 and 8 illustrate use
FIG. 9. Basic "and" gate.
FIG. 10. Basic "or" circuit.

of a semiconductor diode in a d-c level restorer and a ring modulator or chopper, respectively.

Logic circuits using diodes may be considered another class of switching applications. Since diodes have two distinctly differing impedance levels, they lend themselves to use in performing predetermined decision or logic functions just as switches or relays may. Figures 9 and 10 show two basic logic functions which may be performed with diodes. Very complicated logic circuits involving many thousands of diodes have been assembled for use in electric computers. These examples indicate the ability of such circuits to make "logical decisions" based on "instructions" built into the particular circuit.

In the case of Fig. 9, all three diodes are normally biased "on" (conducting), d_3 serving to clamp the output to "zero"[1] or ground. If d_1 or d_2 is biased "off" by applying a positive or "one" pulse to one input, the other diode continues to conduct and the output remains at "zero." However, if both d_1 *and* d_2 are turned "off" by positive input signals the output also becomes positive, indicating a "one" stage. That is, a positive pulse or "one" appears at the output only if a one is applied to inputs 1 *and* 2.

[1] In Boolian, or binary, algebra the terms "one" or "1" and "zero" or "0" are used to indicate a "high" or "low," or "on" or "off" condition in a particular logic block or stage.

In the case of the particular "or" circuit of Fig. 10, both diodes are normally "off" and the output is a zero unless a positive pulse is applied to either input 1 *or* 2, in which case the diode conducts and a "one" appears at the output.

10. Choice of a Switching Diode. In general, a low forward voltage and low reverse leakage at the peak "on" current and peak "off" voltage are required.

A diode may be considered a good switch if:

1. The peak "on" voltage (at a specified "on" current) is much less than its peak "off" voltage.
2. Its reverse leakage (at the specified "off" voltage) is much less than the peak "on" current, *i.e.*, $V_{on} \ll V_{off}$ and $I_{off} \ll I_{on}$.

Germanium diodes are generally better than silicon as high-current low-voltage switches because of their low forward voltage, though silicon types are better for high-voltage low-current applications, as they have lower reverse or "off" leakage current, equivalent types assumed.
FIG. 11. Dynamic impedance characteristics, 1N527.

11. Variable-resistance Diodes. A forward-biased diode has an incremental series resistance which is inversely proportional to forward current or voltage. By varying the forward bias current by a suitable means, a diode may be used as a variable-resistance element in many applications. Figure 11 shows a graph of dynamic resistance as a function of current for one such diode (small-area type) which is controlled for this characteristic.

12. Variable-capacitance Diodes. The capacitance of a reverse-biased diode varies inversely with voltage (approximately as the inverse square root), and by varying this reverse voltage the diode shunt capacitance can be varied electrically. Thus such diodes can be used as "reactance tubes" in suitable circuits. Figures 12 and 13 show the voltage-capacitance curve for a large-area diode and a basic voltage-tunable circuit in which such a diode may be used.
FIG. 12. Variation of capacitance of germanium junction diode vs. reverse bias voltage.

13. Frequency Multipliers or Harmonic Generators. Semiconductor diodes may be used as the nonlinear element in harmonic-generating circuits. For example, the output of a tube or transistor oscillator operating at moderately high frequencies is fed to a diode which feeds a circuit resonant at a harmonic of the oscillator frequency (*e.g.*, a v-h-f oscillator used with a diode to drive a u-h-f tank circuit).

In general, the output of such a circuit is relatively low when high multiplication factors are used but is usually high enough for low-level converter applications. Multiplication factors on the order of 3 to 5 are practical, though diode performance may be variable at higher values unless diode types having specified performance characteristics are used.

A typical frequency-multiplier-circuit arrangement is shown in Fig. 14.

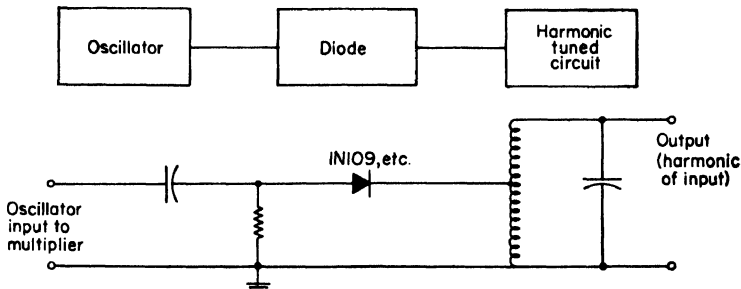
14. Frequency Converters. Semiconductor diodes are used over a very wide frequency range (a-f to microwave) as frequency converters. Circuit considerations are similar to those involved in design of circuits for use of thermionic diodes. For linear conversion or detection, oscillator injection current should be much larger than the
FIG. 13. Junction diode used as voltage-variable capacitor.


FIG. 14. Diode frequency multiplier.

signal current. At high frequencies the low capacitance of semiconductor diodes, especially of point-contact types, is desirable.

15. Semiconductor Diodes as Thermistors. Semiconductor diodes may be used as either low-impedance or high-impedance (current sources) thermistors by operating them in the forward or reverse directions, respectively. Forward-biased diodes have voltage saturating characteristics above their knee voltage and may be used as reference or regulating devices. However, this forward saturation voltage varies with temperature, the coefficient being approximately −2.5 mv per °C for germanium and −1.7 mv per °C for silicon. These values may vary somewhat with the design of the diode but indicate that diodes may be used as compensating elements where a negative voltage coefficient is desired.

Diode thermistors differ from the conventional type in that the characteristic is nonlinear, and if a-c signals are involved, they may be useful only at levels below their knee voltage. If the peak signal swing exceeds this value, distortion will result from nonlinear operation, or if operated on the plateau region, very little variation in dynamic resistance will be obtained even though the plateau voltage is shifting (and

the d-c resistance with it). At low levels, where a-c operation is practical, the voltage coefficients are variable with voltage and are lower than the values indicated above.

Thus, the diode thermistor is more useful in d-c compensation circuits. One specific application is the use of a diode in the base bias network of transistor circuits to improve temperature stabilization of collector bias current, as shown in Fig. 15 Shaping networks may be used as with thermistors to obtain the desired characteristic
FIG. 15. Variation of forward voltage with temperature and use as thermistor, germanium diode.

Reverse-biased diodes operated in the reverse current saturation region where dynamic resistance is very high may be used as current sources which are temperature variable (Fig. 16). If a voltage which varies over a wide range is applied to such a diode and a series load, the current in the load is nearly constant but follows the temperature law of the particular diode used. Shaping networks may be used to adjust this characteristic as desired.

Diode reverse currents are also discussed in Sec. 28.
FIG. 16. Variation of reverse current with temperature, germanium diode.
FIG. 17. Equivalent circuit of a semiconductor diode.

DIODE CHARACTERISTICS

16. Equivalent Circuit of a Semiconductor Diode. The equivalent electric circuit of a semiconductor diode is shown in Fig. 17. The actual values of the parameters depend upon the particular diode design, which varies considerably. It is important to note that the junction resistance and capacitance are highly variable with bias voltage (see Sec. 11).

At lower frequencies, lead inductance, package capacitance, and junction capacitance can often be neglected so that only the junction and base resistances need be considered for the forward-biased diode. At reverse biases (below breakdown), r_b is negligible compared with r_j, which is typically very large.

At higher frequencies it becomes necessary to consider the effect of other parameters,

and the utility of the diode may be limited by package and junction capacitance as well as lead inductances at several hundreds or thousands of megacycles.

Typical ranges of values of these parameters are (order of magnitude only):

L_l = lead inductance, near zero to several $\mu\mu$h
C_p = package capacitance, 0.5 to tens of $\mu\mu$f
r_b = lead and base resistance, 1 milliohm to 1,000 ohms
r_j = junction resistance (reverse), 10^3 to 10^{10} ohms
(forward), near zero to thousands of ohms
C_j = junction capacitance, 10^{-13} to 10^{-8} farad

17. Selenium Diodes. Selenium diodes are made by placing (usually by evaporation or flow coating) a thin layer of selenium on a backing plate which provides mechanical strength and serves as one electrode. The outer surface of the selenium layer is then treated to form a barrier layer. A pressure, or sprayed metal electrode, provides the second contact. A typical construction is shown in Fig. 2*a*.

Photocells of high sensitivity can be made by applying a transparent electrical contact to this prepared selenium surface. These diodes are normally used as photovoltaic cells but may occasionally be used as photoresistive devices. Selenium diodes
FIG. 18. Microwave detection diodes.

have relatively high reverse leakage and capacitance and are therefore most widely used in power-frequency rectification applications. Miniature designs, however, may be useful as high-frequency detectors and in other medium-speed applications in which germanium point-contact and small-area junction types are normally used. Forward conductance and rectification efficiency are much lower than those of equal-area germanium or silicon devices.

Failure of selenium rectifiers, when it occurs, is normally caused by a gradual reduction in forward conductance caused by reduction in contact area as elemental diodes become open-circuited, which results in increased forward dissipation (load current assumed constant). This in turn causes increased reverse leakage and dissipation leading to runaway and catastrophic failure ("burnout"). This is in contrast to the case of germanium- and silicon-junction diodes where increasing reverse leakage is the most significant cause of failure.

18. Silicon-junction Diodes. Silicon-junction diodes are available in alloy, grown, or diffused types of structures and in a wide range of sizes and ratings. They are of particular interest because of their very low reverse leakage and saturation currents, their abrupt reverse voltage breakdown, and the ability to withstand higher temperatures than those made of other common materials. A disadvantage in some low-voltage applications is the high "knee" voltage of the forward characteristic, approximately 0.7 volt vs. 0.3 volt for germanium.

Reverse leakage resistances are several orders of magnitude greater and reverse saturation current several orders of magnitude lower than those of germanium. Thus silicon diodes are highly desirable where very low reverse leakage is required (see Sec. 28).

The reverse breakdown voltage may also be as high as several thousand volts (per cell) in certain designs. The abrupt breakdown characteristics for which some designs are noted permits their use in various reference and regulating applications.

19. Silicon Reference or Regulating Diodes. Silicon-junction diodes may exhibit very abrupt reverse saturation or "breakdown" voltage characteristics. Such diodes may be used as sources of reference voltages or as shunt regulators in the same manner
Fig. 19. Forward and reverse characteristics of a silicon reference diode.

as certain gas-filled tubes. The characteristic of a typical silicon reference diode is shown in Fig. 19. Note that the relatively high starting voltage needed for the glow-discharge tube is not required.

Diodes are available which have breakdown voltages from 1.5 to 600 or higher. Such diodes may also be biased in the forward direction to obtain voltages of about 0.75 to 1.5, as relatively little conduction occurs at lower voltages. (This is also true for diode types of other basic materials.) It is also possible to construct diodes having forward and reverse characteristics which are more or less symmetrical and which are useful in certain limiting applications (Fig. 20). If the characteristics are not symmetrical, a (reverse) bias voltage can be used to set the quiescent operating point midway between the forward and reverse conduction voltages. Two matched diodes can also be used if connected back to back. Thus these diodes may be used to regulate voltages or as reference voltage sources over a much greater range of voltage than gas tubes.

Fig. 20. Characteristics of diode having symmetrical forward and reverse voltage saturation characteristics.

20. Dynamic Reverse Saturation Impedance. Dynamic reverse impedance varies considerably, being, in general, directly proportional to the breakdown voltage of the particular diode. Table 2 shows typical values of reverse resistance (in the saturation region) for a few of the available types.

The saturation reverse resistance also varies markedly with bias current for a particular diode, being inversely proportional to current over a relatively large range near the "knee," but approaching a more constant value at higher currents.

Table 2. Silicon-diode Reverse Resistance

Diode	Reverse saturation voltage, approx.	Saturation dynamic resistance,* approx. ohms
1N401	1.8	5
1N405	4	10
1N202	12	50
1N207	34	280
1N210	58	750

* At nominal bias current.

21. Reverse Capacitance. Capacitance is not generally important in regulation applications, but reverse capacitance varies approximately as $1/\sqrt{V}$. Manufacturers usually give a nominal value at a particular voltage, commonly 6 volts. $C_{v_2} \approx C_{v_1} \sqrt{V_1/V_2}$, where C_{v_2} is the capacitance to be determined at a voltage V_2, and C_{v_1} is the nominal capacitance given by the manufacturer for a voltage V_1. Forward capacitance is rarely specified and may range from tens of micromicrofarads to thousands of microfarads depending on physical size of the diode and the forward current level; it is directly proportional to both.

22. Reverse-biased Switches. Diodes having abrupt voltage breakdown may be used as switches while biased only in the reverse direction. Operation in a high-impedance or "off" state is conventional, but the "on" or low-impedance state is
FIG. 21. Biasing of a reference diode for use as switch.

obtained by increasing the reverse bias so that breakdown occurs and a high current flows.

If low-voltage regions are avoided, a relatively low capacitance is obtained and, further, very low switching times can be obtained since very rapid changes (tens of millimicroseconds or less) in current may occur in the breakdown region of the characteristic. Figure 21 illustrates this application.

23. Temperature Coefficient of Saturation Voltage. This is usually positive and directly proportional to voltage, at voltages above approximately 4 volts. At lower voltages a negative temperature coefficient is observed. The exact zero-coefficient voltage varies somewhat with manufacturing-process details and is not constant except as a statistical mean for a particular diode type. However, the possibility of series-connecting two diodes having temperature coefficients which more or less cancel one another over a substantial temperature range does exist.

Dissipation Ratings. Currently available types can dissipate up to about ½ watt, but laboratory devices capable of tens of watts dissipation have been constructed and will be available in the future.

A-c Voltage Regulation. This can also be accomplished by using a double peak-

clipping circuit. Either single or multistage clipping can be employed, depending upon the desired degree of regulation, as shown in Fig. 22.

24. Silicon Point-contact Diodes. Silicon point-contact diodes are constructed as two important generic types for use as high-frequency microwave detectors and in the more conventional design as a fast-recovery type which is especially useful in high-speed computer circuits. In appropriate point-contact designs a low-capacitance diode having low storage time and a high rate of recombination of hole-electron pairs may be constructed which may be useful as a detector to 500 Mc or higher without special assembly design.

For use as a microwave detector or frequency converter the diode is normally constructed in a manner suitable for use as part of a transmission line or cable. These diodes vary considerably in design depending upon particular applications and the
Fig. 22. A-c voltage regulation with breakdown diodes. (*a*) Single stage. (*b*) Two-stage arrangement.

characteristic impedance of the transmission line or mixer with which they are to be used. Certain specially designed types may have by-pass capacitance and lead-inductance features incorporated in the diode enclosure itself. See Fig. 18 for examples.

For use as a high-speed switching or computer diode the same characteristics make the silicon point-contact diode extremely useful where rapid reverse recovery is required. Recovery times on the order of hundredths of a microsecond may be realized under practical computer switching conditions. Extreme care is required in measuring transient responses of such short durations. These diodes may be designed to have low reverse leakage at 100 to 200 volts and several milliamperes, or more depending on particular design compromises, of forward conduction at 1 volt. They are normally assembled in small or miniature glass envelopes.

25. Germanium-junction Diodes. Germanium-junction diodes are made in alloy, grown, and diffused versions, the former being the most common, especially in the high-current types. They are made in a wide range of sizes, but most notable are the larger units intended for high current rectification and switching. Their most important characteristics are the high forward conduction, up to hundreds of amperes at ½ to 1 volt, and relatively low reverse leakage currents. The forward "knee" voltage occurs at about 0.3 volt in contrast to that of about 0.7 volt for silicon.

They are, thus, especially useful in low-voltage and/or high-current applications

where the low voltage drop and low dissipation are desirable. In smaller types, low- to medium-speed switching is possible, and high rectification efficiency may be obtained at all power levels with suitable types. In current designs, temperature limitations are, nominally, in the vicinity of 100°C, though there are basic reasons for expecting that this can be increased in the future.

Reverse voltage breakdown is less abrupt and more variable than with silicon; so germanium diodes are seldom used for reference or regulating purposes though they are useful in all other applications within their frequency range.

26. Germanium Point-contact Diodes. *Tungsten-whisker Types.* These diodes are representative of a family of germanium point-contact diodes using unplated whiskers, usually tungsten. These diodes have relatively low forward conductance, 1 to 25 ma approximately at +1 volt, and relatively high reverse leakage. The familiar 1N34 or 1N34A is more or less representative of this generic diode type.

Reverse capacitance of these diodes is relatively low. In certain design variations reverse recovery time is as low as 0.1 to 0.25 μsec, and such diodes are excellent for general-purpose use as high-frequency (to about 300 Mc) detectors and computer diodes. Depending upon the particular diode characteristics specified (forward and reverse conductance, recovery time, etc.) a wide variety of types are available.

27. High-forward-conductance Types. These diodes are known by a variety of designations, such as high conduction, low impedance, plated whisker, and bonded.
FIG. 23. Optimum low-level detector biasing.

They are made by plating the whisker with a metal such as indium or gold and subsequently heating the contact with the germanium die by electrical pulsing to melt the whisker plating and, locally, the germanium die. Recrystallization produces a pseudo-junction type of diode having greater area than before pulsing. This increased area contributes to higher forward conduction, which results from the formation of this crude junction, which also has a lower reverse leakage than a true point contact.

Diodes constructed in this manner have characteristics intermediate to point-contact and alloyed-junction diodes. Forward conduction is usually in the range of 25 to 500 ma at 1 volt, and reverse leakage current may approach that of junction diodes.

Reverse capacitance and recovery time are generally somewhat greater than those of the true point contact. Storage time is also higher, though this is an advantage in diode amplifiers or other applications where this characteristic may be exploited.

Applications. These diodes are generally applicable where point-contact types may be, though not quite so useful in high-frequency and high-speed computer applications. The more abrupt transition into (higher) forward conduction makes them very useful as clamps and low-power rectifiers, but some forward bias is desirable if full advantage of this characteristic is to be taken in detector service (see Fig. 23).

SEMICONDUCTOR DIODE REVERSE CHARACTERISTICS

28. Reverse Current. Reverse resistance in semiconductor diodes is a nonlinear function of voltage and obeys different laws in various voltage regions. These regions are shown graphically for a germanium-junction diode in Fig. 24. In region
FIG. 24. Reverse current in a semiconductor diode.

1 of Fig. 24 up to a few tenths of volts (approximately the barrier potential for the material and temperature involved) the current is composed of thermally generated minority carriers which have diffused to the junction region and are collected there. The charge carriers are hole-electron pairs generated when electrons gain enough thermal energy to escape from their parent atoms, leaving a net positive charge called a hole which may be filled by another electron. For a given temperature there are only a limited number of thermal carriers available and a reverse current saturation results at about 0.3 and 0.7 volt, respectively, in the cases of germanium and silicon, respectively.

FIG. 25. Reverse resistance of a semiconductor diode.

At higher voltages, reverse current still increases (region 2 of Fig. 24) but does so more slowly. This is due to surface or body leakages, which are usually nonohmic, though they may be ohmic over a fairly wide voltage range in some cases. At still greater reverse voltages, the reverse current increases very rapidly (region 3 of Fig. 24) because of one or more diode-breakdown phenomena. In certain diodes, this breakdown is quite abrupt and a negative resistance region may be observed—perhaps leading to excessive dissipation and possible catastrophic failure of the diode.

In the region of normal reverse operation, the reverse junction current may be approximately given by $I = I_s + V/R$ (Fig. 25). In the cases of some junction diodes and most point-contact types, the incremental resistance is nonohmic and

linear extrapolations cannot be used in predicting reverse current at one voltage from that at another. For a perfect junction, this resistance would be infinite.

I_s is a function of temperature and can be predicted fairly accurately if known for one temperature. The incremental leakage resistance is commonly a function of temperature but varies considerably depending upon the individual device and type of device.

For germanium: $$I_{sT} \approx I_{sT_1} \times 2^{\frac{T_2 - T_1}{10}}$$

For silicon: $$I_{sT} \approx I_{sT_1} \times 2^{\frac{T_2 - T_1}{5}}$$

where $I_{sT_2} = I_s$ at temperature T_2.

The behavior of reverse current in semiconductor diodes is similar to that of collector or emitter reverse currents in transistors.

29. Reverse Breakdown (Voltage Saturation). Reverse voltage breakdown may be caused by one or more factors. In general, if diode temperature is limited to rated values, no impairment results from excursions into the breakdown region. The most important causes of reverse voltage saturation or breakdown follow.

Zener or Field Emission. In Zener breakdown electrons are torn from their atomic bonds by the high electric field across the junction. These electrons may then cause secondary emission, and a cascade or avalanche type of breakdown may then be involved as well.

Avalanche. Avalanche breakdown occurs when available electrons (as thermal charge carriers) gain enough energy in traversing the junction to cause secondary emission and a cascade or avalanche results. This mechanism is similar to that of ionic glow discharges in gases. In nonuniform junctions (as in point-contact devices) avalanches may occur first in localized high-field regions, progressing to others as the field increases and a "soft" or rounded breakdown characteristic results.

Punch-through. As reverse voltage is increased, the junction-depletion layer widens and, if no other breakdown processes intervene, may eventually, at a lower voltage, include the entire base or die thickness. Further increase in voltage cannot then cause a further increase in junction thickness and the electric field increases more rapidly until it induces breakdown.

Surface Breakdown. As very high electric fields exist across the surface, as well as in the interior of the diode, breakdown or leakage may occur at the boundary of the junction and its ambient. Conductive contaminants if not completely eliminated may contribute to high reverse leakage currents or a lower breakdown voltage. High-voltage low-leakage diodes are often coated with or encased in materials having good dielectric qualities to minimize these effects.

It is frequently very difficult to say with certainty which of these mechanisms is causing reverse breakdown or saturation in a particular diode or transistor, as failure may be caused by any one or a combination of several of these mechanisms if critical dissipation levels are exceeded. In certain cases localized burnout and progressive deterioration may result if nonuniform junction temperature occurs.

Thermal Breakdown or Runaway. The reverse current in semiconductor devices varies in an exponential manner with temperature. Further, the temperature depends upon the dissipation, which is a direct function of reverse current and voltage.

As voltage is increased (and with it reverse current) the dissipation rises and with it junction temperature, and at some critical dissipation and temperature this regenerative situation leads to an unstable or runaway condition. This critical point is that at which

$$\frac{dT}{dP}\frac{dP}{dT} > 1$$

where dT/dP = rate of increase in temperature with dissipation
dP/dT = instantaneous rate of increase of dissipation

For a constant reverse voltage $dP/dT = V(dI_R/dT)$. Then the temperature at which $dI_R/dT > (1/V)(dP/dT)$ is the runaway point. Thus, if the dP/dT and dI/dT characteristics of the individual device are known, its runaway temperature can be determined. These characteristics are frequently available from the manufacturer and are implicitly given in his ratings. The former is sometimes quite uniform for a type of device, while the latter varies widely with individual units. For nearly ideal junctions at voltages below breakdown, I_R may be used to compute approximate critical or runaway temperatures. Typical forms of these characteristics are shown in Figs. 26 and 27. Note that widely different curves (only two of which are shown) for dI_c/dT may result, depending upon the temperature relationships of the various components of the reverse current.

FIG. 26. Junction temperature rise vs. dissipation; air cooling.

FIG. 27. Typical form of junction reverse current vs. temperature.

DIODE RECOVERY TIMES

When a semiconductor diode is switched from the "on" to "off" state, the transition from a high (forward) current to a low reverse current is not instantaneous but requires a finite period of time. Similarly, a transition from "off" to "on" is not instantaneous, though this time is often short enough that it can be considered negligible.

As a relatively long time is required for such switching transients to disappear completely, it is conventional to term the period between 10 and 90 per cent of final current or voltage values as the "switching" or "recovery" time, or, in appropriate cases, "turn-on" or "turn-off" time. Recovery to a specified reverse-current or resistance (large-signal) value is also a commonly measured time.

It may be desirable to test the diode in an actual circuit and determine the time required for recovery to a specified current or voltage, implicitly to a minimum large-signal resistance. The test circuit is usually the actual circuit or is related to that in which the diode is ultimately to be used. It is also possible that a rectification-efficiency test at a suitable frequency will correlate with actual switching-time measurements or, perhaps, be acceptable when time cannot be measured simply or accurately.

30. Forward-recovery or Turn-on Time. This is the time required for an "off"-biased diode to switch to an "on" or high-conduction state. The diode under test is usually biased off by a fixed voltage and is pulsed on by a high-impedance or current source. The voltage across the diode is observed on a suitable oscilloscope, preferably one with a time-calibrated sweep. The oscilloscope's vertical amplifier must have a transient response considerably shorter than the diode recovery time to be measured.

The voltage waveform across a typical computer diode is shown in Fig. 28. A commonly used test circuit is also shown. The turn-on time is commonly defined as the time required for the voltage to return to less than a specified value. Alternatively, time is not actually measured, but a maximum peak forward voltage may be specified. In the case of certain high-speed diodes, there may be no visible overshoot, indicating that turn-on time is less than the oscilloscope's response time.

31. Reverse-recovery or Turn-off Time. This is the time required for an "on"-biased diode to switch to an "off" or high-impedance state. The diode under test is
normally biased on by a fixed current and is pulsed off by a low-impedance pulse generator. The time required for reverse current to recover to an arbitrary fraction of the final value or, commonly, to a fixed value is measured on a calibrated oscilloscope. The wave form of reverse current, as measured across a series resistance, and a suitable test circuit are shown in Fig. 29.
FIG. 28. (*a*) Forward-recovery-time test circuit. (*b*) Diode forward current during pulse conduction.

The pulse of reverse current is a result of storage of minority carriers in the base region, which must be collected at the oppositely biased region. In cases where forward dissipation is significant, thermal recovery is also involved. When times of less than 0.1 μsec are to be measured, great care must be given to designing the test circuit so that diode and not circuit response is measured. Major difficulties may be associated with:

1. The signal source. A fast rise time is required of the applied step function. Suitable pulse or square-wave generators or relay contacts may be used.
2. The scale-switching diode must have low capacitance and a short recovery time, preferably much less than that of the diode under test.
3. The oscilloscope amplifier and display circuits should have a sufficiently rapid response.

FIG. 29. Diode reverse recovery current.

All these factors may introduce time constants on the order of 10 mμsec or more so that recovery times of 25 to 100 μμsec can be measured only with some difficulty and potentially significant errors. When recovery times of less than about 50 μμsec are to be measured, a rectification-efficiency test should be considered as the circuit is simple and dependent mainly on the test diode's response, which usually correlates well with performance in the switching circuit.

32. Diode Detection or Rectification Efficiency. A test of diode rectification efficiency is very useful in evaluating the utility of a diode as either a detector or rectifier if made under conditions representative of its intended use. It may also be invaluable in estimating performance of a fast-recovery switching diode. Test conditions of importance are the use of (1) signal source of a suitable frequency, (2) output level,

(3) a filter output circuit realistic in terms of the actual operating circuit, and (4) suitable indicating meters.

A basic rectification-efficiency test circuit is shown in Fig. 30. The filter capacitor and load resistance are chosen for the desired time constant and power consumption. The meter may be a d-c VTVM or a simple resistance-current meter combination, sometimes used as a load as well. In certain detector applications a modulated input
FIG. 30. Basic circuit for testing rectification efficiency.

signal and an a-c voltmeter are used. A high-Q tank circuit may be used to filter the input current so that it may be more readily measured, when the wave form of diode current is not readily determined or will load the source unduly.

In evaluating computer diodes, a frequency of tens to hundreds of megacycles is often used, and where desired the output capacitance may usually be made as low as that of the circuit in which the diode is to be used. This is a relative advantage compared with the classical recovery-time-measuring circuits discussed where many large time constants limit measurements. Correlation of rectification efficiency with time measurement can usually be made in the 50- to 150-mμsec range and extrapolated to considerably lower values.

TEMPERATURE EFFECTS

33. Cooling of Power Diodes. Certain diodes do not have sufficient cooling capacity inherent in their package design, and these must be attached to cooling structures
FIG. 31. Temperature gradients involved in power diode cooling.

or have a current of air forced past them. It is important to remember that internal-temperature-gradient coefficients of dissipation are limiting factors over which only the manufacturer has control and that the user must determine actual dissipation in his application and provide sufficient cooling capacity so that maximum rated junction temperature is not exceeded.

Junction temperature is given by the formula in Fig. 31. Temperature-gradient coefficients must be obtained from the manufacturer and determined by the user for
FIG. 32. Temperature derating of diodes.
FIG. 33. Improved uniformity of diode forward characteristics when series resistance is added.

the cooling structure to be used. This rise in temperature is analogous to a rise in voltage when a current is fed to a series of resistances. In this case, dissipation and temperature-gradient factors are analogous to current and resistance, respectively. The various coefficients are physically associated with diode construction and mounting in Fig. 31.

The temperature-gradient coefficients may be nonlinear and vary with temperature. This is especially so in the case of fluid convection and radiation cooling (see Fig. 26), and static values at arbitrary or limiting values of junction and ambient temperatures are often quoted in manufacturers' literature.

Figure 32 illustrates the typical form of power-diode temperature derating. Actual maximum temperature limits are quite variable depending on type, as are the slopes of the derating curves. Some manufacturers permit linear extrapolation to low temperatures, but in some cases constant maximums may be established.

SHUNT AND SERIES OPERATION

Occasionally, because of the limitations of ratings, it is necessary to operate diodes in shunt to obtain higher current capacity or in series to obtain higher inverse voltage ratings. In such cases, the diode forward or reverse conductances must be carefully matched and remain matched during their life, or unequal sharing of dissipation results, leading to the failure of some or all of the diodes involved.

34. Shunt Operation. Where two or more diodes are shunt-operated to increase their allowable output current, voltage across them is equal, and if current flowing is
FIG. 34. Improved uniformity of operation with series diodes plus shunt admittance.

not also equal, the diode having the higher forward conductance carries a higher fraction of the output current and must dissipate more heat than the other. In many diodes, the higher temperature of the better diode further increases its conductance and its temperature, leading to early failure if it cannot carry almost all the load alone.

When the added voltage drop may be tolerated, diodes having poorly matched or nonuniform forward characteristics may be shunt-operated if a resistance is inserted in series with each diode. If this resistance is five to ten times greater than the internal (incremental) diode resistance, the effective uniformity of the diode characteristics is improved and parallel operation with uniform sharing of load current is possible.

Certain silicon diode types may be exceptions, as their forward resistance increases with temperature, tending to compensate for nonuniformities, and little if any series resistance may be needed. Where dissipation in the series resistances is excessive, inductive ballasts may be used instead where a-c or pulsed voltages are applied.

Figure 33 shows the forward characteristics of two germanium diodes having different incremental resistance above the knee with and without added series resistance.

35. Series Operation. When two or more diodes are operated in series to obtain higher breakdown voltage, the current in all diodes is equal, and unequal distribution of reverse voltage results if the reverse characteristics of the diodes are not uniform throughout life.

Where the increased current can be tolerated, resistances may be added in shunt with each diode. Where dissipation in the shunt resistances may be excessive, capacitive voltage dividers may be used instead when a-c or pulse voltages are applied.

The resistance values should be chosen so that the resistor current at peak voltage is much greater than that in the diode, preferably five to ten times.

Figure 34 shows the characteristics of two diodes with and without their shunt resistors. Note the improved division of the applied voltage.

FIG. 35. Photocurrent characteristics of a typical selenium photovoltaic diode.

PHOTODIODES

Photodiodes are two-element, light-sensitive devices which (1) generate a voltage or (2) undergo a change in effective resistance when exposed to light. Accordingly they may be termed photovoltaic or photoresistive, respectively. Many semiconductor photodiodes may be operated in either manner, *e.g.*, selenium is useful in a light meter as a self-generating photocell but may also be used with external bias as a photoresistive cell, while cadmium sulfide is used only as a sensitive photoresistor.

36. Photovoltaic Diodes. Photocurrent characteristics of a typical selenium photodiode are shown in Fig. 35. Note that this is a relatively low internal-impedance device and that output voltage tends to saturate at high light levels and is on the order of 0.25 volt. Silicon and germanium photovoltaic diodes will deliver approximately the same output voltages under load conditions, though open-circuit voltages are in the 0.25- to 0.5-volt range. Multiple stacks may be used to obtain higher voltages and currents for various applications. Spectral response of a selenium photocell is shown in Fig. 36. The peak response corresponds to that of the human eye.

37. Photoresistive Diodes. Photo characteristics of a typical germanium photoresistive diode are shown in Fig. 37 (in the case for a small-area germanium-type 1N77B). Voltage and current output swings can be readily determined from these curves if bias-voltage, load-line, and light-input excursions are known.

Dark current is equivalent to junction-leakage current, as discussed in Sec. 28, and at normal temperatures is lowest for silicon and progressively higher in germanium or selenium and other compounds.

Cadmium sulfide is notable for its high sensitivity, which is due to an inherent current-multiplication effect. Spectral sensitivity of germanium and silicon diodes is given in Fig. 36.

FIG. 36. Spectral response of semiconductor photodiodes.

38. Frequency Response. Frequency response of photocells depends upon their construction, point-contact types having good high-frequency response, while large-area junction types are relatively poor. Certain selenium cells have very slow transient recovery, *e.g.*, those having time constants as high as 1.0 to 100 sec or more.
FIG. 37. Photo characteristic of a typical germanium photoresistive diode.

39. Temperature Stability of Photodiodes. Temperature stability of photovoltaic cells is on the order of about 0.1 to 5 mv per °C. In the case of photoresistive types silicon and germanium are relatively stable though dark current varies in the same manner as reverse leakage (see Sec. 28). Other types have been somewhat less stable and may be unusable with d-c amplifiers when exposed to large temperature variations if the dark current is a significant fraction of the light current.

CHAPTER 10

TRANSISTORS

By Seymour Schwartz[1]

In many ways the development of the transistor has paralleled that of the vacuum tube as the latter is known today.

In 1883, Edison discovered that a unidirectional current would flow through a two-electrode evacuated enclosure. Not until 1904 was any practical use made of this discovery. Then Fleming applied it to the detection of wireless signals. In 1906, De Forest added a third or control electrode to the simple Fleming valve, thereby making a simple rectifier into an amplifier and, as a consequence, into an oscillator.

The discovery of the fact that metals in contact with certain "semiconductors" would conduct current asymmetrically seems to go back to Munck in 1835. This rectifying action was utilized by Pickard, who, in 1906, patented the crystal detector. His "cat-whisker" device was widely used until it was replaced by De Forest's triode. Then the crystal diode virtually disappeared until it was resurrected and improved during the Second World War.

Just as De Forest's grid made possible totally new devices and applications, so the addition of a third electrode to a cat-whisker crystal detector has brought about a vast and important development.

First announced in 1948 by Brattain, Bardeen, and Shockley, the crystal detector with two cat whiskers became the transistor. Theoretical work by Shockley and many others plus experimental work of countless engineers and scientists have brought the device to the point where it is exceedingly useful. The art is already complex but still fluid so that the transistor picture today may not be at all what it will be a few years hence.

So rapid has the development been that the first type of transistor—the point-contact type—has already been put aside in favor of newer and better types.

1. Basic Transistor Theory. Certain elements have electrical resistivities intermediate between good conductors and good insulators. In general the resistivity of these semiconductors increases with increasing temperature.

A transistor is a device made from such a semiconductor, notably silicon or germanium, in which certain impurities have been incorporated. Some impurities, such as arsenic or antimony, known as *donors* can act as suppliers of electrons; others such as gallium and indium and known as *acceptors* can act as suppliers of positive charges.

Materials having an excess of negative charges (electrons) are called *n-type* materials; and those which have an excess of positive carriers are called *p-type* materials.

In *n*-type materials, the *majority* carriers are electrons; in *p*-type materials the majority carriers are *holes*. Conversely in *n*-type materials the *minority* carriers are holes and, of course, in *p*-type materials the electrons are minority carriers. In transistors it is the minority carriers that are controlled and provide the useful amplification.

Current through the device is considered as being conducted by the electrons and by holes which are created when an electron breaks free from the crystal in which it normally resides. Conduction in transistors cannot be explained simply by the

Table 1. Transistors, Types and Characteristics*

Device property \ Process	Doped grown	Rate grown	Surface barrier	Fusion
Region resistivity:				
Emitter	Very low	Moderately low	....	Very low
Base	Moderately low	Moderately high	Moderately low	Moderately high
Collector	High	Moderately high	....	Very low
Region size:				
Emitter	Large	Large	....	Thin
Base	Thin	Thin	Very thin	Thin
Collector	Large	May be quite thin	....	Thin
Limitations on alpha	Carrier transport and surface recombination	Emitter efficiency, carrier transport, and surface recombination	Emitter efficiency	Carrier transport, side diffusion, and surface recombination
Limitations on low r_b'	Spreading resistance from point (poor ohmic)	Spreading resistance from point and moderately high base resistivity (poor ohmic)	Very thin web	Thin web
Limitations on max collector voltage	Bulk and/or surface breakdown	Bulk and/or surface breakdown	Surface breakdown and/or punch-through	Punch-through
Phenomena limiting R_{re} (dynamic)	Surface only	Surface and some space-charge widening	Surface and space-charge widening	Space-charge widening and some surface
r_c	Very high	High	Low	Moderately high
Alpha crowding	Good	Probably poor	Not of concern due to power limitations	Good
Collector series resistance R_{cs}	High	Moderate to low	Very low	Very low
Power capabilities	Only fair	Only fair due to alpha crowding	Very low due to small areas	Good for geometry reasons
f_{co}	High 5–10 Mc	High 5–10 Mc	Very high (Ge) 50–150 Mc	Moderate 1.5–5 Mc
Collector capacitance	Low due to high collector resistivity and grated junction	Low due to high collector resistivity	Low due to small size	Moderate high due to low collector resistivity, larger collector than emitter and step jn.
Emitter inverse voltage	Low due to bulk breakdown	Moderate low due to bulk breakdown	Low due to surface breakdown	High, same as collector
Max collector voltage	Ge, 30–70 volts; Si, 80–120 volts	Low	ca. 6 volts	Ge, 30–70 volts; Si, 30–200 volts
Emitter-to-collector shorting capacitance	Appreciable due to base contact overlap	Appreciable due to base contact overlap	Very low	Very low
Emitter floating potential	High (due to base channel)	High (due to base channel)	No such effect	No such effect
Collector low-voltage saturation characteristic	Poor due to high R_{cs}	Probably moderate to good	Good	Good

movement of electrons, and the hole concept of the conduction theory seems well established.

2. Point-contact Transistor. The first type of transistor, now outmoded, was the point-contact type consisting of a slab of the semiconductor called the *base*, and two cat whiskers, called the *emitter* and the *collector*. In a general way these electrodes correspond to the grid, the cathode, and the plate of a triode vacuum tube, but the

correspondence is not complete or exact. The transistor output characteristics resemble those of a pentode vacuum tube.

3. Junction Transistor. Nearly all the transistors in use today are of the junction type in which, for one example of construction, a sandwich is made of a *p*-type material between two slices of *n*-type material or the converse, that is, a slice of *n*-type material between *p*-type slices. In either case the middle material forms the base, and if this is of *n*-type material, then the device is called a *p-n-p* transistor and if the base is *p*-type, then the device is an *n-p-n* transistor.
FIG. 1. Transistor geometry.

4. Transistor Characteristics. Because the transistor is small, because no stand-by heat is required to make it function when needed (there is no heated cathode or filament), because of the elimination of microphonics, because there is considerable power gain, and because there is very little reason for it to wear out, the transistor has become an electronic tool with very great possibilities.

There are some disadvantages, however. One is the fact that, even though biased in the reversed direction, a small steady current flows from an electrode to base whether there is any input driving power or not. The disadvantage comes not from the loss of efficiency or wastage of power or production of heat to be dissipated but

Table 2. General Distinguishing Characteristics of Junction Transistors*

Transistor groups	Major characteristics that distinguish type numbers	Most commonly used types	Typical range of max collector dissipation, mw	Typical range of max collector voltage breakdown, volts	Typical range of max I_{co}, μa	Typical range of C_c, μμf	Typical range of β (α_{cb})	Typical range of $f_{\alpha_{co}}$, Mc
Low-frequency low-power	Low α, β; medium α, β; high α, β; low noise	*p-n-p* fused Ge, *n-p-n* grown Ge	50–150	30–50	3–10	3–20	30–100	0.5–1.5
Low-frequency low-power high-temperature	Low α, β; medium α, β; high α, β	*n-p-n* grown silicon, *p-n-p* fused silicon	50–150	30–50	<0.1	3–10	15–50	0.3–2
Low-frequency high-power	Medium p_c, high p_c, value of β at high I_e	*p-n-p* fused Ge	100–20,000	20–60	20–2,000	25–400	5–50	0.01–0.2
High-frequency low-power	Medium $f_{\alpha_{co}}$; high $f_{\alpha_{co}}$; value of $R_{b'}C_c$	*p-n-p* fused Ge, *p-n-p* surface barrier Ge, *n-p-n* tetrode Ge, *n-p-n* grown Ge	20–50	6–30	1–10	2–15	30–100	1–100
High-frequency low-power high-temperature	Medium $f_{\alpha_{co}}$; high $f_{\alpha_{co}}$; value of $R_{b'}C_c$	*n-p-n* grown silicon, *n-p-n* grown tetrode silicon	20–50	6–30	<0.1	2–10	15–50	1–50

* As used in sine-wave circuit applications.

from the fact that this continuous current flow is strongly temperature-dependent, approximately doubling for each 10°C rise in temperature. If not taken into account in circuit design, these variations with temperature may cause trouble, in d-c amplifiers as one example. Another disadvantage is the dependence of collector capacitance on variations of collector voltage and base current.

Transistor fabrication is still an art, and some manufacturers continue to rely on selection techniques in sorting production into type-number categories. It must be realized, however, that even today some of the most important tube parameters are not held in manufacture to tolerances closer than about 20 per cent, and numerous parameters are not controlled at all.

5. Transistor Types. The literature and circuitry of transistors are already complex. Numerous types of the devices are available, their names and characteristics, advantages and disadvantages being functions of their structure. Only time will tell which of the large number now at hand will survive and which will fall by the wayside. Six of the common types are shown diagrammatically in Fig. 1, and Table 2 gives the distinguishing characteristics. In general the majority of these types of transistors may be classified into one of five major categories: (1) low-frequency, (2) high-frequency, (3) power, (4) low-frequency high-temperature,

and (5) high-frequency high-temperature types. This chart also points out the major characteristics that normally distinguish the units listed. It is of interest to note that, in general applications, most of the transistors in each of the respective categories are fairly interchangeable. Other information listed includes the types of transistors most commonly used and typical ranges of some of their more important characteristics.

6. Basic Operation. In a very elementary way the principle of transistor action may be explained as follows. Each of the end regions (Fig. 3), for example, forms with the base a diode rectifier with considerably greater resistance if biased in one direction than if biased in the opposite direction. The diodes are independent of each other except as the conduction of one is affected by phenomena taking place in the base. The resistivity between one end region and base is a function of the bias voltage between these elements and also a function of the voltages applied between base and the other end region.

Power amplification is secured because virtually the same current flows in the output as flows in the input, but the output impedance is higher than that of the input so that the I^2R available output power is greater than that in the input.

Basically the transistor is current-operated in contrast to a vacuum tube, which is voltage-operated. A current gain as high as 100 may be secured in some circuit and transistor configurations.[1]

7. Basic Circuits. Three basic circuits are possible, as shown in Fig. 2, depending upon which two electrodes are the input and which make up the output. One electrode or terminal is common to both input and output.
FIG. 2. Basic transistor circuits.

The *common-emitter* circuit is most widely used. It corresponds to the conventional grounded-cathode vacuum-tube circuit. The *common-base* circuit corresponds to the grounded-grid tube circuit; and the *common-collector* circuit resembles the cathode-follower type of tube circuit.

The common-base circuit has low input and high output impedances, current gain less than unity, and is a good r-f amplifier. Because of the low power gain it is not often employed.

The common-emitter circuit has high current gain, greater power gain than the grounded-base circuit, higher input and lower output impedances than the common-base circuit. The common-collector circuit has considerable current gain and an input impedance considerably higher than the output impedance. These relative characteristics may be summarized as follows:

	Current gain	Power gain	Input impedance	Output impedance
Common base	Low*	Intermediate	Lowest	Highest
Common emitter	High	Highest	Intermediate	Intermediate
Common collector	High	Lowest	Highest	Lowest

* Normally less than unity.

[1] For a more detailed and accurate explanation of the basic phenomena the reader should consult the references at the end of this chapter or D. G. Fink, Transistor Electronics, "Standard Handbook for Electrical Engineers," 9th ed., McGraw-Hill, 1957.

8. Junction Transistor Action. In Fig. 3 consider a junction transistor as being made of three slabs of material, a *p*-type base in the center with *n*-type emitter and collector materials on either side of the sandwich (grown-junction type).

Consider now the situation at the interface of the *p-n* junction (on the right). Without any bias potential being applied, the *majority* carriers (electrons in the *n*-type and holes in the *p*-type material) traverse the junction (*diffuse*) in equal numbers per unit of time. Thus there is no net current flow.

Now, if the *p*-type material, as shown in Fig. 3, is biased positive with respect to the base, carriers, positive and negative, move across the junction and a current made up of the sum of the carriers flows. The hole current, however, is greater than the electron current because the resistivity of the *p*-type material is lower. In the *n*-type material the holes injected across the interface are *minority* carriers. Because of the relatively enormous numbers of majority carriers in the *n*-type material, the holes are not subjected to any very great individual potential and they slowly diffuse through the material, recombining with negative carriers, with the result that the hole current gradually decreases. If the *n*-type material is thin so that most of the holes can get across it before recombining, the decrease in hole current is not so great.

FIG. 3. Geometry and bias conditions for grown-junction transistor.

If the junction is biased in the other direction, so that the *n*-type material is positive, electrons move away from the junction. The *p*-type material will now be negative and the holes move away from the junction on its side of the interface. With such a bias, very little current flows in either direction, perhaps only 1/100,000 of that flowing in the forward bias direction. Some current, however, always flows because of thermally energized carriers. This is the *saturation current* I_{co}.

The action at the other junction, the *n-p*, is exactly the opposite of that just described. The difference between the two junctions lies in their relative resistivities. The minority carriers diffuse through the material of the higher resistivity and the forward current direction is that in which the higher-resistance material is attractive to minority carriers. Thus the *n*-type terminal will be negative and the *p*-type terminal positive when the junction is biased for forward current flow.

9. Definitions. The following definitions are those of the principal electrical quantities or parameters encountered in transistor literature and employed in the remainder of this discussion.[1]

α = small-signal common-base short-circuit current gain $= \left.\dfrac{i_c}{i_b}\right|_{V_c=0}$

β = small-signal common-emitter short-circuit current gain $= \left.\dfrac{i_c}{i_e}\right|_{V_c=0}$

I_c = collector current
I_e = emitter current
I_b = base current
I_{co} = collector current when the collector is reverse biased and the *emitter* circuit is open at a given value of collector voltage
I_{co}' = collector current when the collector is reverse biased and the *base* circuit is open at a given value of collector voltage ($\doteq \beta I_{co}$)
V_c = voltage, collector to common terminal
V_e = voltage, emitter to common terminal
V_b = voltage, base to common terminal
f_α = frequency at which alpha is 0.707 of its low-frequency value (alpha cutoff frequency)
f_β = frequency at which beta is 0.707 of its low-frequency value (beta cutoff frequency)
C_c = capacitance between collector and base
r_e = small-signal emitter resistance

[1] For a more complete list of quantities and parameters see IRE Standards on Semiconductor Symbols, *Proc. IRE*, **44**, 934, July, 1956.

r_b = small-signal base resistance
r_c = small-signal collector resistance
r_m = mutual resistance (product of alpha and collector resistance)
p_c = collector power dissipation
r_b' = high-frequency base resistance

10. Equivalent Diode Circuits. It is often convenient to picture the transistor as shown in the diode equivalent circuit of Fig. 4. The collector-base and emitter-base junctions are represented by diodes with the collector diode shunted by a current generator αI_e. A resistance r_b represents the resistance of the base region. The circuit is shown for a *p-n-p* transistor; for an *n-p-n* transistor the diodes, voltages, and currents would be reversed.

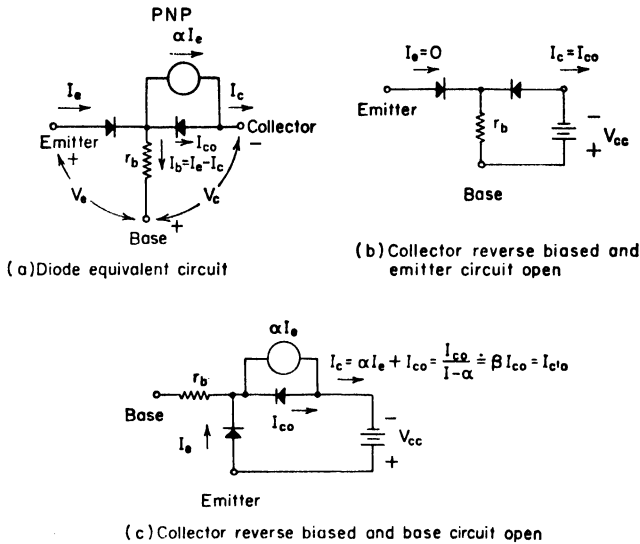
The transistor is normally biased as shown with the collector diode biased in the reverse direction where it shows a high impedance, and the emitter diode is biased in the forward direction where the impedance is low. Ideally the emitter current would


FIG. 4. Diode equivalent circuits.

consist entirely of minority carriers injected into the base region and these carriers would diffuse without recombination to the collector and α would be unity. Actually the emitter is not completely efficient and recombination does take place; so α is less than unity and the difference between emitter and collector current appears in the base lead.

Power gain in the common-base configuration is possible because emitter current injected at the low-impedance level of the emitter circuit appears only slightly diminished at the collector terminal at a high-impedance level. In the common-emitter configuration current gain $\alpha(1 - \alpha)$ as well as power gain is provided. The common-emitter configuration is used most frequently, particularly in low-frequency circuits, because of its higher power gain, current gain greater than unity, and more favorable impedance levels for many applications.

The diode equivalent circuit is valuable in representing the transistor over a wide range of operating conditions and is particularly useful in considering large-signal operation. By considering the diodes to be nonideal junction types having finite resistance, saturation current when reverse biased, and a resistance inversely propor-

tional to current when forward biased, a fairly accurate representation of the transistor is obtained.

Figure 4*b* shows the diode equivalent circuit with the collector biased in the reverse direction and the emitter open-circuited. The current flowing in this connection, termed I_{co}, is made up of the saturation current of the collector diode plus current due to leakage. For reverse biases of more than a few tenths of a volt the saturation current is constant, and for low voltages or low leakage, I_{co} is made up largely of the saturation current. The saturation current is strongly temperature-dependent, approximately doubling for each 10°C increase in temperature. Typical values of I_{co} are 5 to 20 μa for low-power germanium junction transistors at 25°C. For silicon transistors it is much lower, typically of the order of 0.1 μa at the same temperature. The variation of I_{co} is one of the major difficulties in operating transistors over wide temperature limits and is responsible for the possibility of a thermal runaway condition wherein a rise in temperature increases I_{co}, causing an increase in power dissipation resulting in further rise in temperature and I_{co} until the transistor is ruined.

Figure 4*c* shows the diode equivalent circuit with the collector diode reverse biased and the base circuit open. The collector current in this connection is termed I_{co}' and since I_e must equal I_c, I_{co}' must be $I_{co}/(I - \alpha)$, which is approximately equal to $\beta I_{co}[\beta = \alpha/(1 - \alpha)]$. I_{co}' can be very much greater than I_{co} because beta may range from 20 to 100 or more. The condition illustrated in Fig. 4*c* is the worst situation as far as collector current variations with temperature and I_{co} are concerned while that of Fig. 4*b* is the best. In actual operation, with typical bias arrangements, conditions are intermediate between those of Figs. 4*b* and 4*c*.

$\bar{\beta} = \frac{\bar{\alpha}}{1-\bar{\alpha}} \cong \frac{1}{1-\alpha}$ when value of $\bar{\alpha}$ is close to 1

$\bar{\beta}$ = D-C value of β

$\bar{\alpha}$ = D-C value of α

FIG. 5. Collector output characteristics for junction transistors, d-c conditions.

11. Characteristic Curves. Figure 5 shows the curves of collector I_c current vs. collector voltage with emitter and base currents as parameters and showing the effects of I_{co}. Also given are the important d-c relationships. Figure 6 shows actual collector characteristics for a typical germanium-junction transistor. In Fig. 6*a*, for the common-base connection, note that the curves do not break until the collector-base voltage is reversed, implying that the transistor may be operated at very low collector-to-base voltages. The slope of the common-base curves represents a much higher resistance than for the common-emitter circuit and the current gain for the common-emitter circuit $\left(\beta = \left.\frac{\Delta I_c}{\Delta I_b}\right|_{V_c} = \frac{\alpha}{1 - \alpha}\right)$ is much greater than the current gain for the common-base circuit $\left(\alpha = \left.\frac{\Delta I_c}{\Delta I_e}\right|_{V_c}\right)$.

(*a*)

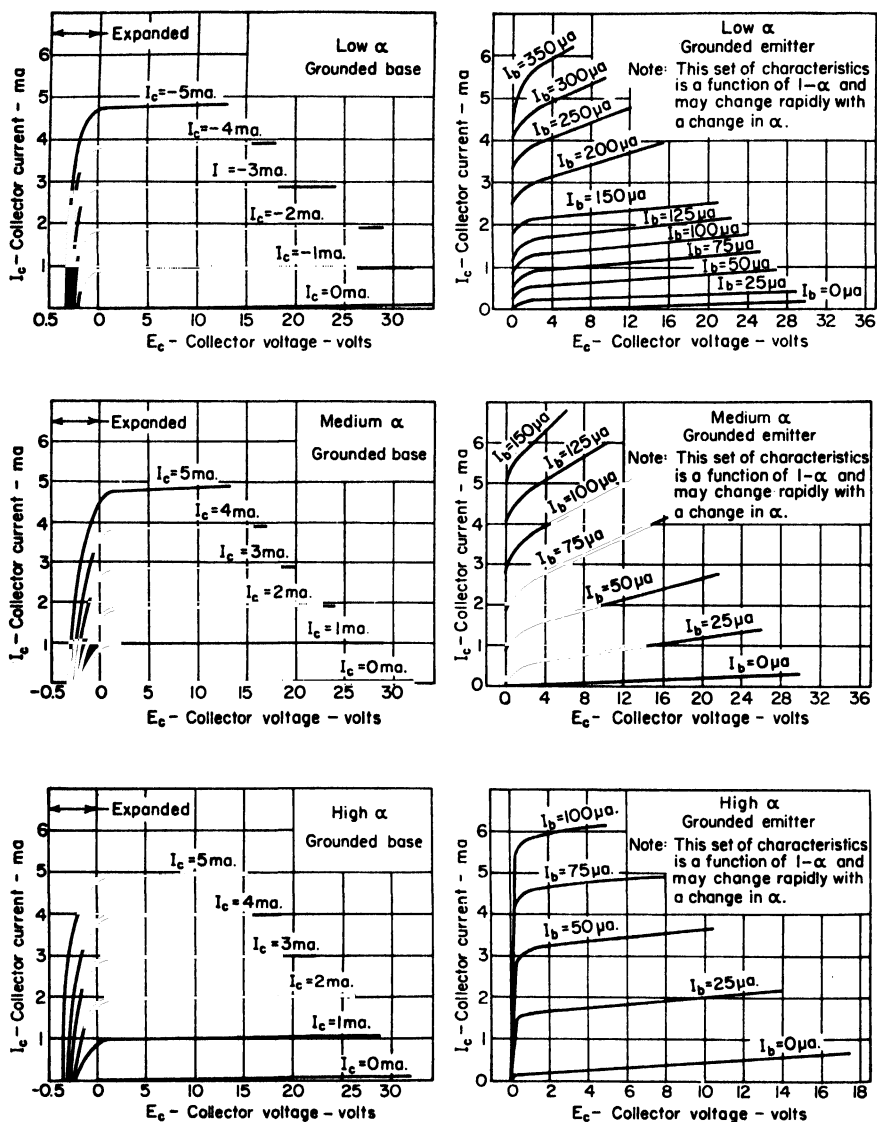
(*b*)
FIG. 6. Collector characteristics of typical germanium-junction transistor, RCA 2N77.


FIG. 6c. Output characteristic curves for *n-p-n* low-power, low-frequency grown-junction triode transistors. (*Texas Instruments, Inc.*)

Figure 6*c* shows a family of output curves for both the grounded-base and grounded-emitter circuits for low-, medium-, and high-alpha conditions.

Examination of Fig. 6 shows that collector voltage is a function of both collector current and emitter current (or base current). Similarly, emitter voltage is a function of emitter current and collector current. That is,

$$V_e = F_1(I_c, I_e)$$

and

$$V_c = F_2(I_c, I_e)$$

when currents and voltages are total values. For small variations in the independent variables,

$$\Delta V_e = \left.\frac{\Delta V_e}{\Delta I_e}\right|_{I_c=\text{const}} \times \Delta I_e + \left.\frac{\Delta V_e}{\Delta I_c}\right|_{I_e=\text{const}} \times \Delta I_c$$

$$\Delta V_c = \left.\frac{\Delta V_c}{\Delta I_e}\right|_{I_c=\text{const}} \times I_e + \left.\frac{\Delta V_c}{\Delta I_c}\right|_{I_e=\text{const}} \times \Delta I_c$$

where the Δs indicate small changes. The ratios of changes in voltage to changes in current may be identified as incremental resistances and changes in voltages and currents as small-signal variations about the bias values. Then the above equations may be written as

$$V_e = r_{11}I_e + r_{12}I_c$$
$$V_c = r_{21}I_e + r_{22}I_c$$

where the voltages and currents are now small-signal values. A small-signal common-base equivalent circuit for the transistor may be made using the r parameters as given above and shown in Fig. 7.
FIG. 7. Two-generator small-signal common-base equivalent circuit.

12. Impedance, Hybrid, and Admittance Parameters. The low-frequency r parameters may be determined from the characteristic curves of the transistors. R_{11} is the slope of the V_eI_e curve for a constant collector current, r_{12} is the ratio of the change in emitter voltage for a small change in collector current for a constant value of emitter current, r_{21} is the ratio of the change in collector voltage for a small change in emitter current for a constant value of collector current, and r_{22} is the slope of the V_cI_c curves for constant emitter current. The two-generator equivalent circuit of Fig. 7 is not too convenient and the T equivalent of Fig. 8a is most frequently used.

Table 3. Relation between T-equivalent Parameters and r and h Parameters

Parameters of T-equivalent circuit	Common-base parameters		Common-emitter parameters	
	r	h	r	h
α	$\approx \frac{r_{21}}{r_{22}}$	$-h_{21}$		
$\beta\left(=\frac{\alpha}{1-\alpha}\right)$			$\approx \frac{r_{21}}{r_{22}}$	h_{21}
r_e	$r_{11} - r_{12}$	$h_{11} - \frac{h_{12}(1+h_{21})}{h_{22}}$	r_{12}	$\frac{h_{12}}{h_{22}}$
r_b	r_{12}	$\frac{h_{12}}{h_{22}}$	$r_{11} - r_{12}$	$h_{11} - \frac{h_{12}(1+h_{21})}{h_{22}}$
r_c	$r_{22} - r_{12}$	$\frac{1}{h_{22}}$	$r_{22} - r_{21}$	$\frac{1+h_{21}}{h_{22}}$

Other equivalents are shown in Fig. 8b for the different transistor configurations, and Table 3 is useful for determining the elements of the T equivalent from the r and h parameters for the common-base and common-emitter circuits. Table 4 gives the relationships between the r, h, and y parameters to the elements of the T-equivalent circuit.

The common-base h parameters are arrived at in a process similar to that used in obtaining the r parameters by considering collector voltage and emitter current as independent variables. The h parameters are particularly useful in making measurements on junction transistors because of the high impedance of the collector circuit and low impedance of the emitter circuit under normal bias conditions.

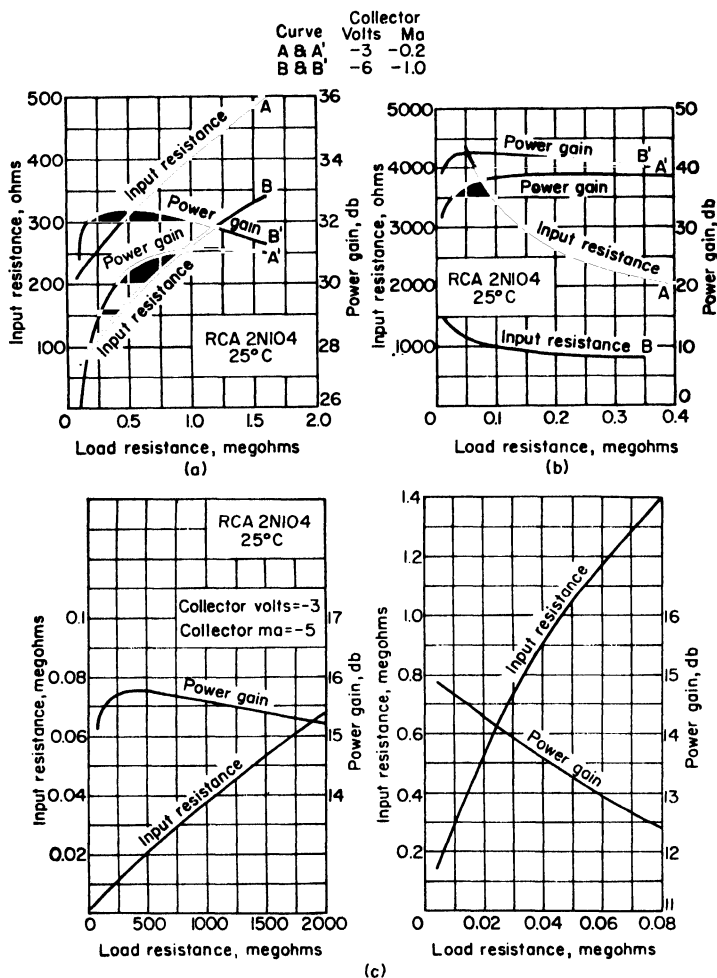
a function of load resistance for a typical audio transistor for the three configurations. The maximum for power gain is quite broad, indicating that the load resistance for maximum gain is not critical. The input resistance increases with increasing load resistance for the common-base circuit, whereas the opposite is true for the common-emitter circuit. In both instances the input resistance is increased and the gain


FIG. 11. Gain and input resistance of typical audio junction transistor. (*a*) Common base; (*b*) common emitter; (*c*) common collector.

decreased as the emitter current is decreased. The input resistance for the common-collector circuit is almost directly proportional to the load resistance [approximately $R_L/(1 - \alpha)$] and high input resistances may be achieved.

14. Temperature Effects. The stability of the operating point of a transistor amplifier with changes in I_{co} due to temperature changes and in replacing transistors is an important consideration in biasing transistors. The magnitudes of the effect of these changes are a function of the biasing circuits. The transistor is normally biased

at the mid-point of the collector load line, but changes in temperature or replacement with another transistor will cause the operating point to change and may result in clipping of a portion of the signal or in extreme cases may result in the transistor's being saturated or cut off. Figure 12 represents the d-c circuit of the transistor (any configuration) with supply voltages shorted. R_b represents the d-c resistance seen in the base circuit (Thévenin equivalent resistance) plus the internal base resistance.
FIG. 12. Bias source resistance.
FIG. 13. Circuit for determining effects of I_{co} on operation for equivalent of Fig. 12.

R_e is the resistance seen in the emitter circuit plus the internal emitter resistance; R_L is the d-c resistance seen in the collector circuit. Figure 13 is an equivalent circuit of Fig. 12 with the assumption that the collector resistance is much larger than R_L, which is usually the case.

The factors which relate changes in bias conditions with changes in I_{co} may be obtained from Fig. 12, where it is seen that

$$I_b = \frac{R_e}{R_b} I_e \qquad I_b + I_e = I_c$$

(using current directions shown in Fig. 12) and $I_c = \alpha I_e + I_{co}$. Using these relationships, the expression $I_e = \dfrac{I_{co}}{(1 - \alpha) + R_e/R_b}$ is obtained which may be differentiated with respect to I_{co} to obtain the stability factor for emitter current:

$$S_e = \frac{\delta I_e}{\delta I_{co}} = \frac{1}{(1 - \alpha) + R_e/R_b} \quad \text{or} \quad \frac{R_b}{(1 - \alpha)R_b + R_e}$$

S_e gives the change in emitter current for a change in I_{co} for a particular biasing arrangement assuming that other parameters have not changed (for example, if S_e is 10 and I_{co} changes by 10 μa because of a change in temperature or substitution of a similar transistor except for a difference in I_{co}, then the emitter current would change by 100 μa).

Differentiating the expression $I_c = \alpha I_e + I_{co}$ with respect to I_{co} gives the collector-current stability factor

$$S_c = \frac{\delta I_c}{\delta I_{co}} = \alpha \frac{\delta I_e}{\delta I_{co}} + 1 = \alpha S_e + 1$$

or

$$S_c = \frac{R_b + R_e}{(1 - \alpha)R_b + R_e}$$

In a similar manner the stability factor for collector voltage V_c may be obtained and is

$$S_v = -(R_L S_c + R_e S_e) = \frac{-(R_b R_L + R_b R_e + R_e R_L)}{(1 + \alpha)R_b + R_e}$$

The stability factor should be low to minimize variations in operating point with temperature or in replacing transistors. Examination of the expression for S_c shows that, for large R_b (constant base current bias) or for small R_e, S_c approaches $1/(1 - \alpha)$, which may be very large (of the order of 50), and for small R_b or large R_e approaches 1. The stability of the operating point is thus improved by keeping R_b, the d-c resistance in the base circuit, as small as possible and R_e, the d-c resistance in the emitter circuit, as high as possible. This is most easily accomplished in transformer-coupled circuits. It is more difficult with RC-coupled circuits because, in the common-emitter and common-collector circuits, the base bias network shunts the input to the

transistor. Making S small requires more d-c power; so a compromise is made between stability of operating point and power dissipation in the bias network. Typical biasing methods are shown in circuit diagrams of various amplifier circuits to follow.

For circuits having feedback resistances connected between transistor terminals the stability factors should be calculated for the particular circuit.

15. Transformer Coupling. The transistors may be cascaded in amplifier circuits using transformer, impedance, RC, or direct coupling or combinations of these. With transformer coupling gain may be achieved with all three configurations with the common-emitter circuit providing the most gain and the common-collector circuit the least. Transformer coupling has the advantages of providing an impedance match between output of one stage and input of the next stage leading to maximum power

(a) Common-base circuit with two battery supply

(b) Common-base circuit with single battery supply

(c) Common-emitter circuit with two battery supply

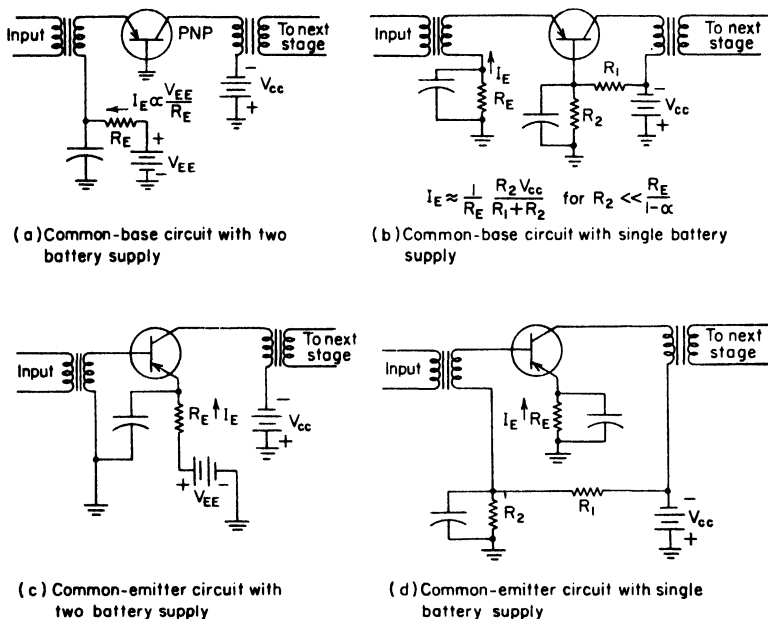
(d) Common-emitter circuit with single battery supply


FIG. 14. Transformer-coupled transistor circuits.

gain, simplifying the problem of stabilizing the transistor against changes in the operating point with temperature and transistor parameter variations, and providing high efficiency. The disadvantages include the expense, weight, and bulk and the limited frequency response of transformers. Because of the high output impedances of the common-base and common-collector circuits it is not always practical to match impedances since this may lead to a situation where the maximum collector voltage is exceeded at the output voltage peaks. The impedance-coupled circuit has the advantage of high efficiency operation but does not permit matching impedances and therefore cannot be used in the common-base configuration. Figure 14 shows typical transformer-coupled circuits and bias arrangements.

16. RC Coupling. In resistance-capacitance coupled circuits only common-emitter and common-collector configurations provide gain when connected in cascade, the common-emitter circuit being most widely used in intermediate stages because of its higher gain (typically of the order of 30 db). The maximum power gain may not be obtained in RC-coupled circuits because input and output impedances cannot be

matched but the loss is not excessive and is compensated by the circuit being less expensive, lighter, and more compact. The choice of input stage depends upon the input impedance desired: for low input impedance the common-base configuration is indicated (provides impedance match but no gain); for intermediate values of input impedance, the common-emitter circuit and, for high values of input impedance, the common-collector stage are best. In the output stage the common-collector provides a low-impedance output, the common-emitter an intermediate value of output impedance, and the common-base circuit a high output impedance. The power gain of a multistage amplifier (ratio of output power to input power) is given by $A_i^2R_L/R_{in}$,
(a) Microphone preamplifier
(b) Portable phonograph amplifier

FIG. 15. Circuits illustrating RC coupling.

where R_L is the output load resistance, R_{in} is the input resistance of the first stage, and A_i is the product of the current gains of the individual amplifier stages.

Circuits illustrating RC coupling are shown in Fig. 15. Figure 15a shows an amplifier having 49 db gain from a 500-ohm source to a 5,600-ohm load and a frequency response flat within 0.5 db from 20 to 20,000 cps. The 0.02-μf capacitor in shunt with the 330-ohm resistor in the emitter circuit is to compensate the drop in gain of the transistor at high frequencies.[1]

In the circuit of Fig. 15b a high input impedance is obtained by placing an unbypassed resistor in the emitter circuit [appears at the base circuit as $R_e/(1 - \alpha)$] of the

[1] Stark, H. F., Transistor Preamps, *Audio*, April, 1956.

first stage and returning the 10,000-ohm bias resistor to the emitter. The bias stability is improved, at the expense of some degeneration, by connecting the base bias divider to the collector.

In RC amplifiers the low-frequency cutoff is determined by the coupling capacitor and input and output resistances of the coupled stages (assuming that bias resistors in the emitter circuit, etc., are adequately by-passed). The frequency at which the response is down 3 db from the mid-band value is given by

$$F_L = \frac{1}{2\pi C(R_o + R_i)}$$

where F_L is the low-frequency 3-db point, C is the capacitance of the coupling capacitor, R_o is the output resistance of the driving stage (essentially the collector load resistance, which is much smaller than the transistor output resistance in most instances), and R_i is the input resistance of the driven stage. The high-frequency cutoff is determined for the most part by the cutoff frequency of the transistor, f_β for common-emitter and common-collector stages and f_α for common-base stages $[f_\beta = f_\alpha/(1 - \alpha_0)]$, where α_0 is the low-frequency α.

17. Direct Coupling. Transistors may be coupled directly to provide gain down to d.c. or to minimize the number of components. The principal difficulty with

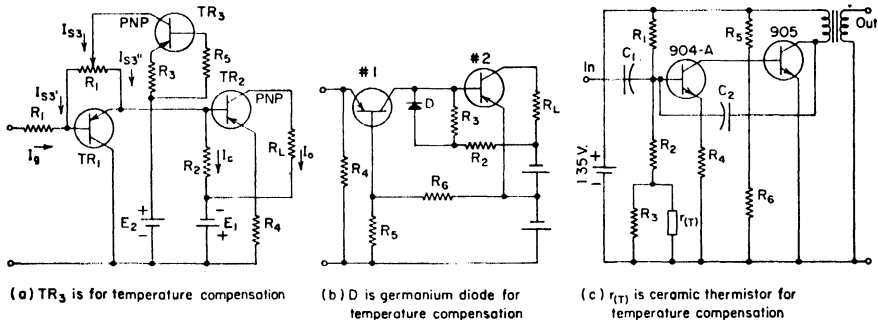
(a) TR₃ is for temperature compensation (b) D is germanium diode for temperature compensation (c) $r_{(T)}$ is ceramic thermistor for temperature compensation


FIG. 16. Amplifiers employing direct coupling.

direct-coupled circuits is the drift in operating point with changes in temperature or transistor parameters, particularly in the first stages of a multistage circuit since bias changes in these stages appear amplified in the succeeding ones. One method of compensation is to use configurations in which changes in I_{co} with temperature tend to balance out (see Table 6). For a two-stage amplifier the condition for this type of stabilization is

$$A_{i2}S_1i_{co1} + S_2i_{co2} = 0$$

where A_{i2} is the current gain of the first stage, S is the stability factor (ratio of change in output current to a change in I_{co}), and i_{co} is the change in I_{co} and the number subscripts refer to stage number. This condition leads to the permissible arrangements shown in Fig. 16 for this type of temperature compensation. This method is not entirely practical since it involves sorting transistors according to I_{co} and placing them in the proper stage. Other means for temperature compensation are to use temperature-sensitive elements such as transistors, semiconductor diodes, thermistors, or other temperature-sensitive resistances. Some practical amplifiers having direct coupling are shown in Fig. 16, and in Fig. 15*b* the driven and output stage are direct-coupled.[1] The problem of I_{co} variations is minimized by use of silicon transistors in preference to germanium types since I_{co} is much lower. Elaborate means of temperature com-

[1] Stanton, J. W., A Transistorized D-C Amplifier, *Trans. IRE*, **PGCT**, 65, March, 1956 (Fig. 16*a*). Keonjian, Edward, Temperature Compensated D-C Transistor Amplifiers, *Proc. IRE*, April, 1954 (Fig. 16*b*), p. 668; Micropower Audio Amplifier, *Trans. IRE*, Circuit Theory, March, 1956 (Fig. 16*c*), p. 68.

pensation of course is not necessary in environments where the range of temperature variation is not great or where changes in bias conditions due to I_{co} variations are not significant compared with normal bias.

18. Audio Output Power Amplifiers. Power-amplifier stages differ considerably from the small-signal circuits previously described. With small-signal circuits the object is to obtain maximum gain; with power amplifiers the object is to obtain the maximum output power at the highest efficiency subject to the constraints of maximum collector voltage, maximum collector current, power dissipation, and operating temperature placed upon the transistor. In obtaining high power output, the load is much different from the output impedance of the transistor circuit and no attempt is made to provide an impedance match to maximize gain; *i.e.*, because of the constraints mentioned above, loads providing maximum power gain are not consistent with loads giving maximum power output. In power amplifiers, the large signals employed result in variation of the transistor parameters with the signal, thus causing distortion. Large-signal or average values rather than small-signal parameters should be used.

Fig. 17. Output characteristics showing limits of operation.

Transistors having permissible power dissipations as high as about 20 watts and maximum collector currents of up to about 4 amp are available for high-power-output stages.

Figure 17 is a sketch of the output characteristics of a transistor with the limits imposed by maximum power dissipation, maximum collector current, and maximum collector voltage shown. When the area of permissible operation is specified by the

Table 6. Circuit Arrangements in Which I_{co} Variations with Temperature Tend to Compensate

Common-collector	Common-base		

maximum power dissipation, collector voltage, and collector current, the load R_L giving the maximum output is determined by two of these quantities. In Fig. 17 two situations are illustrated by showing the load lines resulting for two values of maximum collector current, $I_{c\,max}$ and $I_{c'\,max}$. The maximum power output is obtained when the collector voltage and current are permitted to reach their maximum values.

This leads to load lines R_L and R_L' for the two cases. Load line R_L is permissible since it falls within the area where the maximum limits of the transistor are not exceeded; load line R_L', on the other hand, would not be permissible since the maximum power dissipation would be exceeded. Therefore, if $I_{c' \max}$ is specified as the maximum collector current as shown in Fig. 17, then the load line for maximum output power is dictated by the maximum power dissipation and either $V_{c \max}$ or $I_{c' \max}$. Because of the dropoff of current gain with high collector currents it is best to operate at low values of collector current. For the situation where maximum power dissipation is a limiting factor a load line R_L'' drawn from $V_{c \max}$ and tangent to the maximum power-dissipation hyperbola is the solution.

19. Power Output. In single-transistor class A amplifiers using a transformer in the output circuit, obtaining maximum power output (peak collector voltage of $V_{c \max}$) means using a supply voltage of $V_{c \max}/2$. If some other supply voltage less than $V_{c \max}/2$ is used, then the maximum output power will be limited by the maximum permissible power dissipation of the transistor or by the maximum collector current.

FIG. 18. Mounting details, Minneapolis-Honeywell power transistor.

If it is assumed that the transistor is driven along the load line from zero collector voltage to zero collector current (which is nearly the case with transistors) then the maximum output power obtainable is

$$P_{0 \max} = \frac{V_{c \max} I_{c \max}}{8}$$

for situations where output power is restricted by the maximum collector voltage and maximum collector current. The load resistance R_L is $V_{c \max}/I_{c \max}$.

The maximum power output, for the situation where the output power is limited by the maximum collector voltage and the maximum power dissipation, is $P_{0 \max} = \frac{1}{2}P_d$ and the load resistance is $R_L = V_c{}^2{}_{\max}/4P_d$, where P_d is the allowable power dissipation. The power output in general, for class A amplifiers with a transformer in the output, in terms of the supply voltage V_{cc} is $P_0 = V_{cc}^2/2R_L$ and the collector voltage swings from zero to $2V_{cc}$ at the peaks. The efficiency of the class A circuit approaches a maximum theoretical value of 50 per cent for an ideal amplifier.

Output power is limited by the maximum allowable collector voltage, current, and power dissipation of the transistor. It is not dependent on matching output impedances and is essentially the same for common-emitter, common-base, and common-collector configurations. The allowable power dissipation is a function of the junction temperature, and the transistor must be derated as the temperature increases in accordance with manufacturer's instructions. Transistors designed specifically for power applications are generally constructed to permit mounting in good thermal contact with a heat sink (such as a metal chassis), as shown in Fig. 18.

20. Output Gain. Power gain, unlike power output, is dependent on the transistor configuration. Approximate expressions for power gain for the three basic transistor configurations are

For the common-base circuit, $$G_p \approx \frac{\alpha^2 R_L}{r_e + (1 - \alpha)r_b}$$

For the common-emitter circuit, $$G_p \approx \frac{[\alpha/(1 - \alpha)]^2 R_L}{r_b + r_e/(1 - \alpha)}$$

For the common-collector circuit, $$G_p \approx \frac{[1/(1 - \alpha)]^2 R_L}{r_b + (r_e + R_L)/(1 - \alpha)}$$

where it is assumed that r_e is much larger than R_L. Figure 19 is a plot of gain vs. load resistance for the three configurations for some assumed values of r_e, r_b, and α. The common-emitter circuit has the highest gain. The common-base circuit has a higher gain than the common-collector for high values of load resistance and lower gain for low values. The gain of the common-collector circuit is relatively independent of load resistance. The choice of circuit configuration is not to be made on the basis of gain alone since distortion is also to be considered. The emitter resistance is inversely proportional to emitter current, thus making the input impedance extremely nonlinear. Alpha drops off at high values of emitter current, causing further distortion. This effect is most bothersome in the common-emitter circuit, where the effect of the decreases in alpha is multiplied. Typical variations in current gain with collector current are shown in Fig. 20.[1] For low- or medium-power amplifiers where the reduction in alpha is not great over the operating range and where the load is sufficiently large to give good gain, the common-base circuit driven from a source of high impedance (to swamp out variations in input resistance) is capable of low distortion. The common-emitter circuit gives the best gain with the most distortion. The distortion in the common-emitter circuit may be reduced at a sacrifice in gain by the use
FIG. 19. Power gain vs. load resistance for the three basic configurations.
FIG. 20. Variation of common-base and common-emitter current with collector current, 70°F. (a) $V_c = 2$ volts; (b) $V_c = -2$ volts.

of feedback; however, the amount of feedback that may be used is limited, particularly in high-power transistors, by the phase shift of alpha and in the output trans-

[1] Mooers, H. T., "Design Procedures for Power Transistors," Minneapolis-Honeywell Technical Report TR 77C, Feb. 1, 1956.

former. For high power output with the associated low load resistance the gain of the common-collector circuit is higher than that of the common-base circuit and has lower distortion, particularly when driven by a low-impedance source. Thus for high power output with large collector-current variations, the common-collector configuration is the most satisfactory compromise between power gain and low distortion. Figure 21 shows some typical class A amplifiers. These circuits are biased at the mid-point of the load lines (also Fig. 15*b*).

21. Class B Amplifiers. Because the stand-by power in class A amplifiers is high and the efficiency limited to less than 50 per cent, class B circuits having low stand-by power and a maximum theoretical efficiency of 78.5 per cent are more suitable in many applications. The class B circuit utilizes transistors in a push-pull arrangement in which the transistors are biased at cutoff so that each transistor alternately amplifies opposite half cycles of the input signal. The same limitations as regards maximum collector voltage, current, and power dissipation of the transistor are to be observed. The collector supply voltage must be less than one-half of the maximum allowable collector voltage since the peak collector voltage reaches a value of twice the supply voltage. The maximum power dissipation should not be exceeded even for short periods with an average dissipation of less than maximum to avoid damage to the
FIG. 21. Typical class A output circuits.

transistor. Strictly speaking, transistor audio amplifiers are not operated as pure class B for the transistors are slightly forward biased to minimize crossover distortion due to the nonlinear transfer characteristic at low signal levels where the transition between one transistor becoming active and the other becoming inactive occurs. This forward bias is quite small, amounting to about 0.1 volt emitter-to-base bias, and reduces the efficiency of the circuit slightly. Typical efficiencies of class B circuits are of the order of 60 to 70 per cent.

Output power in terms of the load resistance and the supply voltage is

$$P_0 = \frac{V_{cc}^2}{2R_L}$$

and the load resistance is $R_L = V_{cc}/I_{max}$, where I_{max} is the maximum collector current desired (at $V_c = 0$). (The collector-to-collector load at the terminals of the output transformer is $4R_L$.) The power dissipated by each transistor is approximately $0.069V_{cc}^2/R_L$ and the d-c power supplied to both transistors is about $0.64V_{cc}^2/R_L$.

For class B circuits the common-emitter and common-collector configurations are most popular, there being little to recommend the common-base circuit. The common-emitter circuit has a higher gain, thus requiring less driving power than the common-collector circuit, which has less distortion. The higher distortion of the common-emitter circuit may be reduced, with the previously mentioned difficulties, by the use of feedback or by use of nonlinear transfer characteristics. On the whole, however, the common-collector circuit appears to be the best compromise between

power gain and low distortion. Distortion in the common-collector circuit is particularly low when driven by a low-impedance source such as a common-collector driver. Another advantage of the common-collector configuration is that the output impedance is low, permitting a better low-frequency response with a given output transformer inductance or the same low-frequency response with a lower primary inductance as compared with the common-emitter circuit. The common-collector circuit requires a high-voltage drive (the output voltage follows the input voltage), thus necessitating a stepup transformer between the driver and the output stage or a higher supply voltage for the driver.

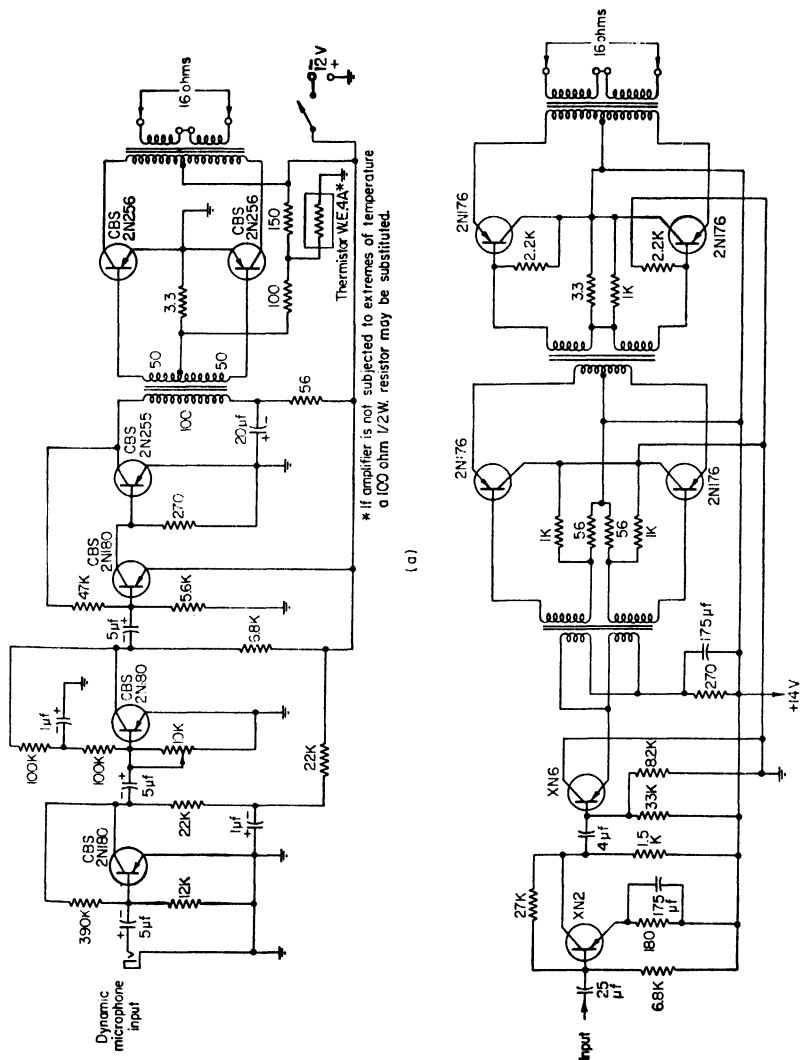
To minimize distortion the transistors should be fairly well matched in variation of current gain with collector current.


FIG. 22. Class B audio circuits. (*a*) 10-watt mobile public-address amplifier with class B common-emitter output. (*b*) 10-watt high-fidelity amplifier with common-collector output. (*c*) Appears on next page.
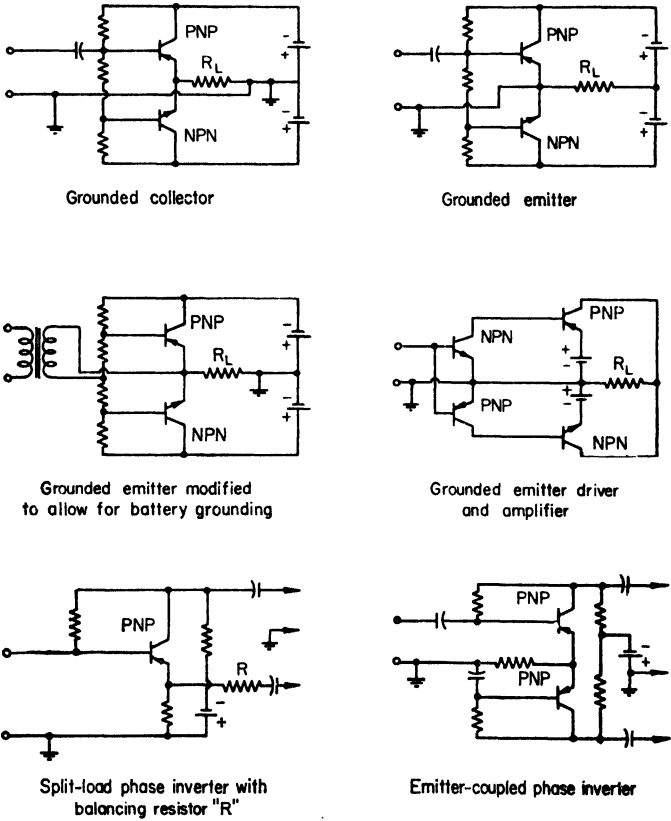
FIG. 22. (c) Distortion vs. output, amplifier of Fig. 22b.


FIG. 23. Complementary symmetry class B circuits and phase-inverter circuits.

A novel class of circuits called *complementary symmetry* circuits results from the availability of transistors in *p-n-p* and *n-p-n* types. These permit push-pull output with single-ended input.

Figure 22 shows some class B audio circuits using transistors of a single polarity type.[1] Figure 23 shows some class B complementary symmetry circuits and some phase inverters for obtaining a push-pull driving source.

HIGH-FREQUENCY AMPLIFIERS

22. Equivalent Circuits. At higher frequencies the equivalent circuits of transistors become more complicated than in the middle range of frequencies where all the elements of the equivalent circuit must be retained. At these high frequencies the equivalent circuit can become simplified and satisfactory results obtained if some of
(a) Complete common-base equivalent circuit and approximate high-frequency equivalent circuit.
(b) Common-emitter equivalent circuit and high-frequency approximation.

FIG. 24. Equivalent circuits and high-frequency approximations.

the resistive elements are dropped from the equivalent circuit. In Fig. 24 the symbols inclosed in parentheses are those sometimes applied to the elements of the equivalent circuit.[2] These circuits are only a few of the many that have been derived to describe the transistor and apply particularly to alloy and surface-barrier types. For some grown-junction transistors the base impedance is complex and for these types r_b' would be replaced by an impedance z_b'.

The equivalent circuits are approximations based on theoretical models. More exact equivalent circuits would involve transmission lines and would not be practical for engineering application.

23. High-frequency Parameters. The important parameters are f_α (alpha cutoff frequency), which should be high, r_b' (base spreading resistance), and C_c (collector-to-

[1] Figure 22*b* and *c* from Crow, R. P., Design of a High-fidelity 10 watt Transistor Audio Amplifier, IRE Convention Record, Part 7, *Audio and Broadcasting*, p. 142, 1956.

[2] Scarlett, R. H., "Some New High-frequency Equivalent Circuits for Junction Transistors," Stanford Electronics Laboratory Report 103, Mar. 20, 1956.

base capacitance), both of which should be low. An approximate expression for high-frequency gain for the common-emitter configuration for transistors having a constant r_b' is[1]

$$G_p \approx \frac{\alpha_0 f_\alpha}{25 f^2 C_c r_b'} \qquad 0.1 < \frac{\omega}{\omega_\alpha} < 2$$

and for grown junctions having a complex base impedance the high-frequency gain is

$$G_p \frac{0.2\omega_\alpha^{1/2}}{\omega^{3/2} C_c (r_b' r_e')^{1/2}} \qquad 0.1 < \frac{\omega}{\omega_\alpha} < 2$$

For both types the gain is dependent on the same parameters but the frequency behavior differs. For the types having a constant r_b', the high-frequency gain drops off 6 db per octave and for the grown-junction type having a complex base impedance the high-frequency gain decreases 4.5 db per octave.
FIG. 25. Single-frequency gain vs. frequency.

24. High-frequency Gain. The low-frequency matched gains for the three basic transistors are, in order of gain, common-emitter, common-base, and common-collector. At high frequencies gains approach the same value and decrease at a 6 db per octave rate. The frequency at which gain is 1 (0 db) may be determined from the expression for gain. This is the maximum frequency at which the transistor can oscillate. The gain vs. frequency may be sketched by drawing a line from $f_{max} = \sqrt{\alpha_0 f_\alpha / 25 C_c r_b'}$ with a -6 db per octave slope to the point where the horizontal line representing the low-frequency gain is reached, as in Fig. 25.

25. High-frequency Impedances. As may be seen from the equivalent circuits, the input and output impedances are functions of frequency (see Fig. 26)[2] and bias conditions. For example, the emitter resistance r_e' is an inverse function of emitter current and the collector capacitance C_c varies as $V_c^{-1/2}$ for alloy or fused-junction transistors and as $V_c^{-1/3}$ for grown-junction units (V_c is collector-to-base voltage).

FIG. 26. Output capacitance and resistance vs. frequency for typical transistor in common-emitter configuration.

26. High-frequency Stability. All three transistor configurations have regions where they are potentially unstable, *i.e.*, passive terminations may be found to cause the circuit to oscillate. The common-collector and common-base configurations are potentially unstable over the whole high-frequency region with the greatest instability exhibited by the common-collector circuit. The common-base circuit has a region of potential instability from about $(1 - \alpha)\omega\alpha$ to a critical radian frequency

[1] Pritchard, R. L., High-frequency Power Gain of Junction Transistors, *Proc. IRE*, **43**, September, 1955.

of $r_e'\omega\alpha/2.4r_b'$, above which it is unconditionally stable.[1] Because of the stability problem unilateralization or neutralization circuits are frequently used in transistor r-f and i-f amplifier circuits. Some grown-junction units are perfectly stable at i-f frequencies yet have good high-frequency performance because of the combination of
FIG. 27. Neutralizing circuits. (a) Common-emitter; (b) common-base.

a high base resistance resulting in a low critical frequency and a very low collector capacitance yielding a low $r_b'C_c$ product.

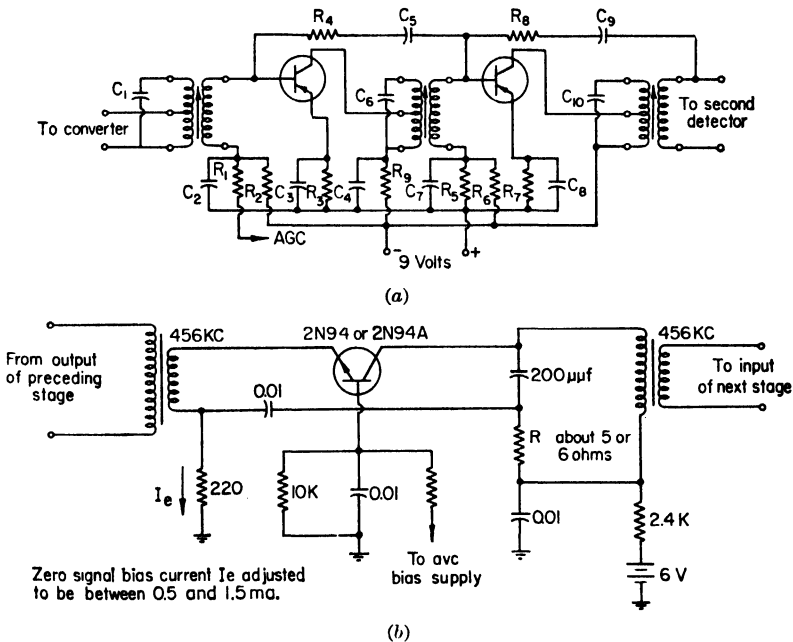
27. Neutralization. Figure 27 shows two of the more frequently used neutralizing circuits. Neutralization also eliminates the dependence of input and output imped-


FIG. 28. Neutralized i-f amplifiers. (a) Neutralized as in Fig. 27a, RCA 2N139; (b) neutralized as in Fig. 27b, Sylvania 2N94.

ances on load and source impedance, respectively, thus simplifying alignment of tuned circuits. I-f amplifiers using neutralizing methods of Fig. 27 are shown in Fig. 28, which also shows the method of automatic gain control commonly used.

[1] Pritchard, R. L., Measurement Considerations in High-frequency Power Gain of Junction Transistors, *Proc. IRE*, **44**, August, 1956.

FIG. 29. Experimental

28. Gain Control. Gain may be controlled by reducing the emitter current with a signal obtained from the detector as the signal level increases. The reduction in emitter current causes an increase in emitter resistance and a reduction in gain. The decrease in gain is due to the decreased amplifying capabilities of the transistor and from a mismatch due to increased input impedance as the emitter current is reduced. Gain may also be controlled by a reduction in collector voltage but the emitter-current control appears more popular. The control signal is generally applied to the base, thus utilizing the d-c gain of the transistor in controlling the emitter current. Difficulties with automatic gain control include changes in band width with signal level and distortion at reduced emitter current, and because of this latter problem AGC is confined to low-level stages. In converter or mixer circuits optimum gain is obtained at a particular value of emitter current and gain control may be achieved by either increasing or decreasing the emitter current about the optimum value.

Single-tuned transformers having tightly coupled secondary windings are the most frequently used method of coupling in transistor i-f circuits. They provide a simple means of obtaining the desired impedance match between the output of one stage (about 50,000 ohms for a common-emitter stage) and the input impedance of the following stage (about 500 ohms for common-emitter). The secondary winding supplies the phase reversal for neutralizing as in Fig. 27*a*. For better selectivity double-tuned circuits, capacitively or inductively coupled, are sometimes used. Gains of 30 db are typical in i-f stages.

For wide-band amplifiers a double-tuned transformer having a capacitor in the secondary resonating with the leakage inductance at center frequency is a good method of coupling and may be designed for a maximally flat response. In common-emitter circuits the primary circuit is often tapped to have a reasonably small tuning capacitor (as in Fig. 27*a*); in common-base circuits the parallel output resistance is higher and desired output Q (about 35 for 456-kc broadcast receiver i.f.s) may be obtained without a tapped primary (as in Fig. 27*b*).

29. Typical Receiver Circuits. Figure 29 is a circuit diagram of an automobile receiver.[1] The r-f and oscillator circuits are permeability-tuned. The i-f stages utilize double-tuned capacitive-coupled interstages and are neutralized. Figure 30 shows a 20-Mc wide-band amplifier having a double-tuned transformer interstage.[2] The primary of the transformer is tuned with the output capacitance of the neutralized

[1] Freedman, Stanley, and Holmes, An Experimental Automobile Receiver Employing Transistors, *Proc. IRE*, June, 1955, p. 971.

[2] Scarlett, R. M., "Some New High Frequency Equivalent Circuits for Junction Transistors," Stanford Electronic Laboratory Report 103, Mar. 20, 1956.

automobile receiver.

common-base transistor and the 36-$\mu\mu$f capacitors tune the leakage inductance of the transformer to the center frequency. The transformers are designed to give a maximally flat band pass.

Circuit diagrams of some commercial receivers[1] are shown in Fig. 31. Circuits *a* and *b* of Fig. 31 use diodes as detectors and the source of AGC signal. In Fig. 31*a* the AGC signal is applied to the converter in a polarity so as to increase the emitter current with an increase in signal level. The AGC signal in Fig. 31*b* is applied to the base of the first i-f and to the combined oscillator and converter from the emitter of the first i-f stage with a polarity so as to decrease the emitter current with an increase in signal (note *n-p-n* transistors used in oscillator-converter and i-f stages). The circuit of Fig. 31*c* has a transistor for a detector, as does the circuit of Fig. 29, but has no
FIG. 30. Wide-band three-stage common-base amplifier.

AGC. The transistor detector has the advantage of giving gain as well as functioning as a detector and supplies power for AGC. The emitter-base diode is given a slight forward bias to bring the operating point near the knee of the emitter-base characteristic. In the circuit of Fig. 29, the AGC signal is taken from the emitter circuit of the transistor detector and applied to the emitters of the r-f and first i-f stages so as to decrease the emitter current with an increase in signal level.

In the circuits of Figs. 29 and 31, the oscillators all operate by inductive feedback from collector to base and in Fig. 31*b* and *c* one transistor performs the function of oscillator and converter. In the circuits of Fig. 31 the r-f signal and oscillator voltage are both applied to the base. In Fig. 29 the r-f signal is applied to the base and the oscillator signal is applied to the emitter. Gains of the order of 15 db are typical of converters. The oscillator coil in receivers is tapped to reduce the effective capacitance of the transistor appearing in shunt with the oscillator tuning capacitor, which

FIG. 31. Commercial transistor broadcast receivers. (*a*) Raytheon, (*b*) RCA, (*c*) General Electric.

is placed across the primary, thus keeping the minimum capacitance obtainable with the tuning capacitor low and permitting the use of a small tuning capacitor. Other oscillator configurations are shown in Fig. 32. Oscillator circuits using vacuum-tube triodes have their transistor counterparts.

FIG. 32. Oscillator circuits.

istic of two video amplifier circuits, both having the same low-frequency gain of 20 db. The common-collector, common-emitter pair has a wider band width than a common-emitter pair. Figure 34 is a circuit[2] of a video amplifier using chokes to improve the band width. The amplifier
FIG. 34. Video amplifier, 9 Mc, 28 db, using surface-barrier transistors.
FIG. 35. Tetrode transistor amplifier; 7 Mc, 500 kc band width, gain > 18 db.

has a gain of 28 db, a band width of 9 Mc with surface-barrier transistors having an alpha cutoff of 45 Mc.

[1] Scarlett, *op. cit.*

[2] Angell, J. B., and F. P. Keiper, Circuit Applications of Surface-barrier Transistors, *Proc. IRE*, December, 1953, p. 1710.

For low radio frequencies (up to a few megacycles) a large number of grown and alloy-type junction transistors are available. Surface-barrier transistors are suitable up to about 20 or 30 Mc. Tetrode transistors are available in both silicon and germanium for amplification at frequencies somewhat higher than 100 Mc. Figure 35 shows the circuit diagram of a tetrode r-f circuit having a double-tuned transformer interstage.[1] Diffused-base transistors have gain beyond 200 Mc but are not presently available.

POWER SUPPLIES AND REGULATOR CIRCUITS

30. Advantages of Semiconductors. The greatest impact of semiconductor devices on vacuum-tube circuitry, probably, has been in the power-supply sections of electronics equipment. Some of the advantages over tube power supplies are reduction in size due to the semiconductor devices themselves, the absence of such bulky components as filament transformers, the minimization of heat generation of the rectifying units due to very low internal resistance of the semiconductor diodes (as low as 1 ohm or less); the increased ruggedness of the supply due to the inherently stable physical structure of the power transistor and power diode; and increased reliability of the supply due to these characteristics and the stable electrical characteristics of the power-type semiconductor units.

The most commonly used power diodes to date have been the fused-junction germanium or silicon units. A typical fused-junction silicon diode may have a peak inverse voltage rating of 500 volts and maximum average forward currents up to 1 amp and

Fig. 37. Shunt-type semiconductor constant-voltage regulators. (*a*) Low power; (*b*) single transistor; (*c*) output voltage control; (*d*) three transistors.

with internal resistances in the order of 1 ohm. The typical full-wave power supplies built with these units are of the 400-watt variety. For higher-wattage power supplies the individual units can be connected in series or parallel combinations (or large single units, now available, can be used). For very high wattage circuits, fan or liquid-cooled stacked units are used.

Before considering the subject of regulated power supplies, one must keep in mind that, because of the very low forward internal resistance of the semiconductor, one

[1] Schimpf, L. G., Tetrode Transistor Amplifiers, IRE-AIEE Conference on Transistor Circuits, February, 1954, pp. 18–19.

can build a brute-force-type supply with an internal impedance of a few ohms and this supply, in combination with a constant-voltage transformer, provides fairly good regulation features by itself. However, as the dimensions of the power transformer and chokes are usually prohibitive, the regulator-type circuit design is preferred.

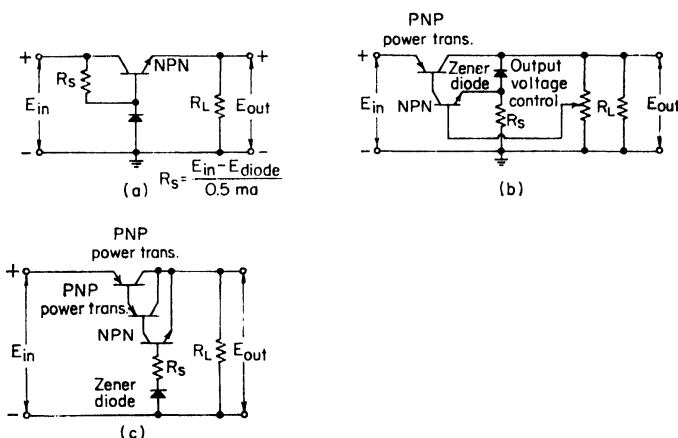
There is a great similarity between the tube regulator circuit and the semiconductor regulator circuit. Where one would use a V-R tube or battery for a constant-voltage reference source in a tube regulator circuit, one would use a "zener" breakdown silicon diode or battery in a semiconductor circuit. Instead of a power pentode as the main regulating device, one would use a power transistor and instead of a high-gain tube for the control and feedback element, one would use a high-gain low-power transistor. The action of the "zener" voltage diode in providing a constant-voltage output over a wide variation of current through it results from the breakdown of a silicon-junction diode when biased in the back direction (see Fig. 36), thus providing the same effect as a V-R tube. The voltage breakdown can be controlled by the manufacturer to occur from a few volts up to a few hundred volts. The current range at each of these voltages is controlled by the maximum power dissipation of the


FIG. 38. Series-type regulators. (*a*) Low power; (*b*) output voltage control; (*c*) three transistors.

units, which is usually 100 mw. Figures 37 and 38 show some shunt and series regulator circuits using diodes and transistors. Figure 39 illustrates the use of semiconductor devices in a large power supply.[1]

TRANSISTOR SWITCHING CIRCUITS

The well-known and well-publicized characteristics of semiconductors make the transistor and diode of tremendous importance in the field of computers. Transistor computers can boast of very small power consumption, small size, and excellent reliability. It must be noted that the transistor cannot yet compete with the speed of vacuum tubes, but the difference in speed between the transistor and tube becomes less each year and in time the transistor will undoubtedly surpass the tube.

31. Binary-system Notation. Electronic computers perform mathematical calculations in a very basic, almost clumsy way. Computers, for example, do not use a decimal system with a base of 10 but use a base of 2.

The decimal number[2] system uses 10 different numbers or symbols which, in appro-

[1] Popp, F. G., "Transistor Regulated Power Supplies," Lincoln Laboratory Report 106, MIT, Jan. 19, 1956.

[2] From B. Dudley.

priate order or arrangement, can be made to represent any finite quantity. The binary number system, on the other hand, uses but two symbols, a 0 and a 1. Any number can be expressed in the binary system of notation, as well as in the decimal system.

FIG. 39. Regulated power supply for magnetic core memory.

In the decimal system, the position of the number indicates the power of 10 which is involved, and the size or magnitude of the digit indicates how many such numbers are to be considered. Thus, the number 751 really means

$$7 \times 10^2 + 5 \times 10^1 + 1 \times 10^0 = 700 + 50 + 1 = 751$$

In the binary system, the position of the symbol indicates the power of 2 involved,

and the symbol indicates whether a 0 or 1 is associated with that power of 2. Thus, when expressed in the binary notation system, 1110 means

$$1 \times 2^3 + 1 \times 2^2 + 1 \times 2^1 + 0 \times 2^0 = 8 + 4 + 2 + 0 = 14$$

The relation between binary and decimal numbers may be made more clear from the following table of equivalents:

Binary Number	Decimal Equivalent
0	0
1	1
10	2
11	3
100	4
101	5
110	6
111	7
1,000	8
1,001	9
1,010	10
1,011	11
1,100	12
1,101	13
1,110	14
1,111	15
10,000	16
etc.	etc.

32. Flip-flop Circuits. The basic building block of electronic computers is the flip flop. The flip flop is a circuit with two stable stages, corresponding to the two symbols used in the binary system. Figure 40 shows a standard transistor flip flop used in early transistor computers.

The cross-coupling resistors R_c and the collector load resistors must comply with the following condition[1]

$$\frac{R_c}{R_L} < \frac{2\alpha - 1}{1 - \alpha}$$

for stability. If this relationship is met, the collector voltage of transistor T_1 will be at one level while the collector voltage of transistor T_2 will be at another level. The collector voltage levels may be reversed by application of pulses to the transistor bases. A logical conclusion is that, by observing the original collector voltage levels, one can tell whether there were an odd or even number of input pulses to the transistor bases. This is a basic mathematical use of the flip flop. A means of counting input pulses will be discussed later, but a discussion of the operation of the flip flop will be presented first to provide a better background.

Referring to Fig. 40, assume that T_1 is "on" and T_2 is "off." The collector voltage of T_2 may be calculated using the equivalent circuit in Fig. 41. T_1 can be included in the above equivalent circuit simply by inserting its equivalent input resistance, which is in parallel with R_{b_1}. The input resistance of T_1 (at the base) is $R_e/(1 - \alpha)$. From the above equivalent network we can calculate V_{c_2} as

$$V_{c_2} = \frac{-V_{cc}\left[R_c + \dfrac{R_b \times R_e/(1-\alpha)}{R_b + R_e/(1-\alpha)}\right]}{R_c + R_L + \dfrac{R_b \times R_e(1-\alpha)}{R_b + R_e(1-\alpha)}} = \frac{-V_{cc}\left[R_c + \dfrac{R_bR_e}{R_b(1+\alpha) + R_e}\right]}{R_c + R_L + \dfrac{R_bR_e}{R_b(1-\alpha) + R_e}}$$

Similarly the collector voltage of T_1 can be found from the equivalent circuit of Fig. 42. The problem is solved more easily by separating the calculation into two parts. First the emitter current of T_1 is found and then using the relationship that $I_c = \alpha I_e$ the effect of collector current I_c on V_{c_1} can be found. In addition V_{c_1} is also part of a simple voltage divider as shown in Fig. 43. The collector current of T_1 is included in the voltage divider to

[1] The following derivations are based on the work of R. E. McMahon, "Transistor Flip-flop Design Techniques," Lincoln Laboratory, *Technical Memorandum* M24-Y2.

show its effect. That part of V_{c_1} due to the voltage divider is the first term on the right of the equation below and that part of V_{c_1} due to I_c is the second term on the right.

$$V_{c_1} = \frac{-V_{cc}(R_{c_1} + R_{b_2})}{R_{c_1} + R_{b_2} + R_{L_1}} + \frac{I_{c_1}R_{L_1}(R_{c_1} + R_{b_2})}{R_{c_1} + R_{b_2} + R_{L_1}}$$

The emitter current I_{e_1} and hence I_{c_1} may be calculated from the equivalent circuit in Fig. 44. The base circuitry can be reduced to a simplified circuit by use of Thévenin's theorem. The equivalent base voltage is

$$V_{beq} = \frac{-V_{cc}R_{b_1}}{R_{b_1} + R_{c_2} + R_{L_2}}$$

The equivalent base resistance is

$$R_{beq} = \frac{R_{b_1}(R_{c_2} + R_{L_2})}{R_{b_1} + R_{c_2} + R_{L_2}}$$

By combining the above a new equivalent circuit (Fig. 45) is obtained. The emitter current is found from

$$I_e = \frac{V_{beq}}{R_e + R_{beq}(1 - \alpha)}$$

Substituting the values for V_{beq} and R_{beq}, I_e becomes

$$I_e = \frac{\dfrac{-V_{cc}R_{b_1}}{R_{b_1} + R_{c_2} + R_{L_2}}}{R_e + \dfrac{R_{b_1}(R_{c_2} + R_{L_2})(1 - \alpha)}{R_{b_1} + R_{c_2} + R_{L_2}}}$$

Using these values,

$$V_{c_1} = \frac{-V_{cc}(R_{c_1} + R_{b_2})}{R_{c_1} + R_{b_2} + R_{L_1}} + \frac{I_{c_1}R_{L_1}(R_{c_1} + R_{b_2})}{R_{c_1} + R_{b_2} + R_{L_1}}$$

as given before.

The normal resistor values used in the circuit result in a voltage level for V_{c_1} of about -5 volts while V_{c_2} is about -10 volts or lower. Complete design equations for a flip flop of this type are found in the references at the end of this chapter. The -5-volt level can be designated as a "0" and the -10 volts can be defined as the "1" symbol.

Fig. 43
Fig. 44 Fig. 45

Figs. 40–45. Multivibrator development.

The above derivations indicate the general method of approach to transistor switching-circuit analysis. A derivation of the base voltages is also important since these voltages, relative to the emitter voltage, determine the stability of the flip flop. In the circuit of Fig. 40 the base voltage V_{b_1} of T_1 must be negative with respect to the emitter voltage V_e for T_1 to be "on" and the base voltage V_{b_2} of T_2 must be less negative than V_e for T_2 to be "off." In notation form, this indicates that

$$V_{b_1} < V_e$$
$$V_{b_2} > V_e$$

These relationships may be simplified to

$$V_{b_1} < V_{b_2}$$

If the voltage relationships V_{b_1} and V_{b_2} are derived and substituted in this equation the stability relationship will result, that is,

$$\frac{R_c}{R_L} < \frac{2\alpha - 1}{1 - \alpha}$$

If the resistor values are chosen in accordance with this equation then the flip flop will have two stable states. Since many resistance values hold for this equation, another relationship is needed to specify either R_c or R_L. Resistor R_L affects the collector voltage levels for both the "on" and "off" transistor, and so it is generally set. A simple relationship useful in determining R_L is

$$R_L = \frac{V_{cc}}{I_e} \times 0.8$$

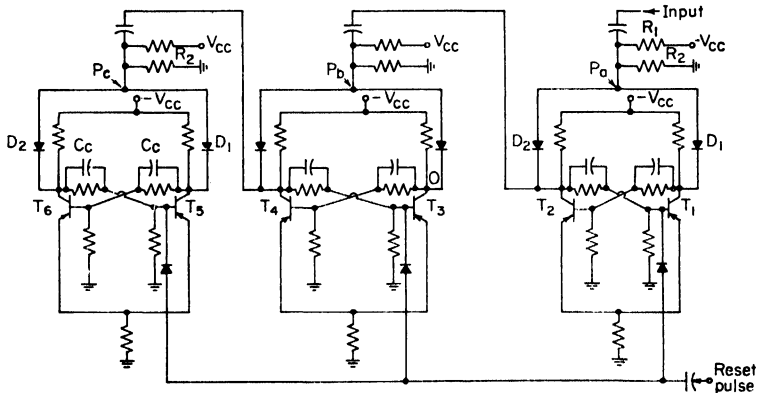
I_e can be chosen to comply with transistor ratings and amount of driving current desired. The multiplying factor of 0.8 is based on advanced design relationships.


FIG. 46. Three-stage flip-flop counter circuit.

Once R_L is chosen, the stability equation may be solved for R_c. The minimum alpha expected for the transistors should be used. R_e affects the emitter current and may be calculated to give the emitter current selected.

The application of a positive pulse to the base of the "on" transistor (T_1) results in a reduction of emitter current and, hence, a reduction of collector current. The collector voltage level of T_1 drops because of the loss of collector current. This voltage drop is coupled to the base of T_2, causing an increase of T_2 emitter current. The emitter current of T_2 builds up, causing the voltage at the collector to rise. This

voltage rise is coupled to the base of T_1, reinforcing the original pulse. After the regeneration is complete the state of the flip flop is changed so that T_2 is "on" and T_1 is "off." The application of a second pulse to the base of T_2 will cause the flip flop to change to the original state with T_1 "on" and T_2 "off."

A diode steering network can be added to the flip flop to steer a chain of pulses alternately to one base and then to the other base. Figure 46 shows a serial counter employing flip flops and diode steering networks. The voltage at the intersection of

the diodes (*Pa*) is set by R_1 and R_2 to equal the "off" transistor collector voltage level. A positive pulse applied to the input will pass through the diode connected to the "off" transistor collector and is coupled through C_c to the base of the "on" transistor, turning the "on" transistor "off." The next input pulse will pass through the opposite diode since it is now connected to the "off" transistor collector. The

Table 7. Desirable Characteristics for Computer-type Junction Transistors

Characteristics	Desirable conditions	Characteristic of germanium units	Characteristics of silicon units	Reason for desirable conditions	Typical triode junction transistor values	
					Germanium	Silicon
Alpha cutoff frequency $f_{\alpha co}$	High	High	High	Higher $f_{\alpha co}$ one of the factors contributing to higher frequency of operation (*i.e.*, faster read-out speed)	2–50 Mc	2–50 Mc
Max collector voltage breakdown $V_{c\,max}$	High	Medium	High	Higher $V_{c\,max}$ makes it easier to drive high-voltage indicators and sources, allows operation from very low V_c region where noise might be a problem	6–40 volts	30–100 volts
Base current amplification factor β at high values of emitter currents	High	High	Medium	Higher value of β at high currents makes for ease in core driving	15–60	5–30
Saturation resistance*	Low	Low	Medium	Low saturation resistance minimizes power dissipation in saturated-type circuitry	30–300 ohms	100–400 ohms
Extrinsic base resistance r_b'	Low	Low	Medium	The lower r_b', the lower the internal losses in emitter follower pulse amplifier, also aids in higher-frequency switching action	30–300 ohms	30–1,000 ohms
Emitter diode reverse breakdown voltage	High	High	Medium	Should be high enough to avoid clipping action† in large single switching applications	20–50 volts	5–20 volts
Collector capacitance C_c	Low	Low	Low	Low value of C_c aids in high-speed switching	7–20 $\mu\mu$f	3–12 $\mu\mu$f
Collector reverse leakage current I_{co}	Low	Low	Very low	Low values of I_{co} ensure maximum stability of operation	1–10 μa	<0.1 μa

† Diode placed in series with emitter lead of silicon transistor will remedy this problem if encountered.

second pulse is coupled to the base of the "on" transistor and turns it "off." The output is coupled to the input of the second flip flop. The positive portion of the differentiated output causes the second flip flop to change states. The timing diagram of Fig. 47 indicates the sequence of events.

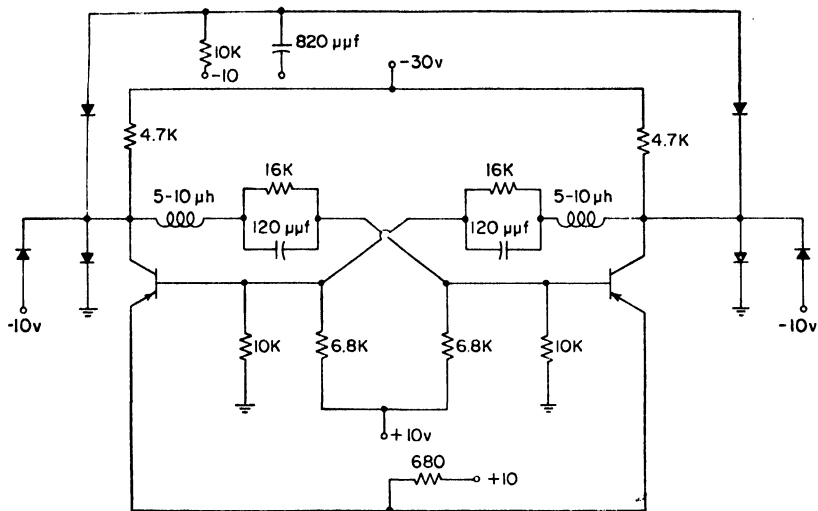
It is common to set the flip flops of a serial counter to a known state before the


FIG. 50. Fast-flip-flop 5-Mc circuit.

application of the input pulses. In Fig. 47 the flip flops were assumed to be set so that T_1, T_3, and T_5 were on. The collector voltage levels are assumed to be 0 volts for the "on" transistor and −10 volts for the "off" transistor. A tabulation of the collector voltages corresponding to the input pulses is shown in Fig. 48. The tabulation may be verified from the timing diagram of Fig. 47.

If we allow the −10 volts to represent the "1" symbol and 0 volts to represent the "0" symbol, it can be seen that the tabulation above corresponds to the binary numbering system. In other words, after 3 input pulses the tabulation shows 0, −10, −10, or 011, which is the number 3 of the binary system. The three-stage counter will count up to 8 and then will repeat. A general formula for the number of stages necessary to count up to x is $x = 2^n$, where n is the number of stages.

The flip flop and serial counter are of basic importance in computers, but additional circuitry, such as shift registers, adder networks, blocking oscillators, and multivibrators is also important. In all these circuits transistors are applicable and are presently in use.

33. Other Switching Circuits. A brief description of transistor circuits other than the flip flops and serial counters is necessary to give a complete picture of switching circuits.

FIG. 51. Typical beat oscillator with self-pulsing controlled by delay line.
"And" and "or" gates are used in many ways, and a description of these gates will indicate their uses. Notice that the "and" gate (Fig. 49) will allow an output

(−10 volts) only if both *A* and *B* terminals are at −10 volts. In the "or" gate, an output occurs at terminal *C* if either *A* or *B* or both are at −10 volts. These gates can be used as control elements and are a necessary part of switching circuitry.

High-speed flip-flop and blocking-oscillator circuits are shown in Figs. 50 and 51.

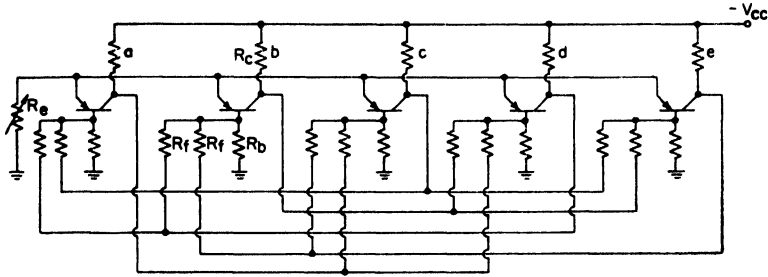
Although the transistor switching circuit is basically an "on-off" device and well adapted to the binary system, other number systems may be used. For example, a counter made up of three flip-flop stages will count to 8 and could be used in systems


FIG. 52. Basic diagram ring-of-5 counter for junction transistor.
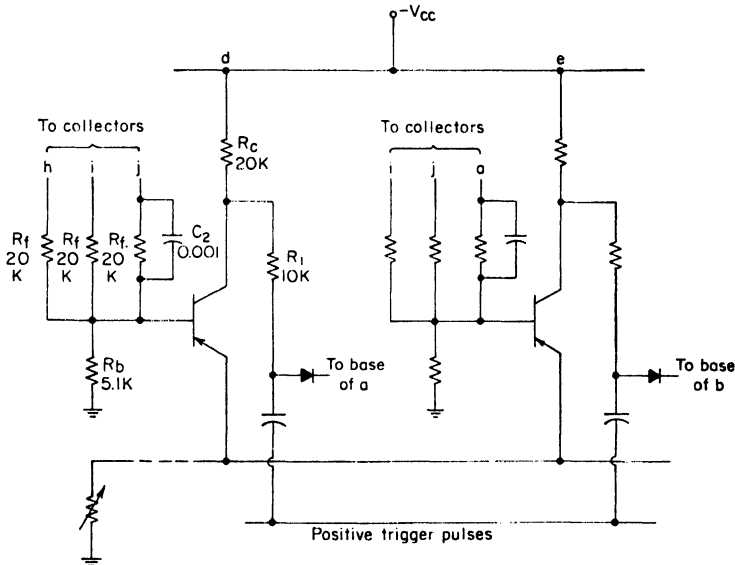

FIG. 53. Gating circuits for the ring-of-5 counter.

operating on base 8, or a four-stage flip-flop counter capable of counting to 16 may be restricted by additional circuitry to cycle at a count of 10, thus operating on the conventional decimal system. Ring counters provide further means of operating with number systems other than binary. Figure 52 shows the basic circuit of a ring of 5 using junction transistors.[1] This is not the conventional circuit commonly used in ring counters seen in tube literature where only one device in the ring is "on" at any time but is one in which, for a five-stage ring, two adjacent transistors are "on"

[1] Carlson, A. W., "A New Ring Counter for Junction Transistors and Vacuum Tubes," *Air Force Cambridge Research Center Report* AFCRC-TN 54-100.

and the rest are held "off" by the "on" transistors. Counters having one transistor (or tube) "on" and the rest "off" would require four resistors of the type labeled R_f and a five-stage ring would be the practical upper limit. By permitting other transistors in the ring to be "on" in a fixed and recognizable pattern of "on" and "off" stages, rings of 10 become practical. The count is indicated by the location of the adjacent "on" transistors in the ring with the location of these "on" stages being shifted by one stage at each successive count. The circuitry for transferring the position of the "on" stages in a 10-stage transistor ring counting positive pulses is shown in Fig. 53.[1] The letters in the diagram indicate the stages labeled a to j. In a 10-stage ring of this type four adjacent stages are "on" and the remaining are "off" at any time. Other types of ring counters may be made up of flip-flop stages and require two transistors per count capability.

Transistor circuitry at present has developed by applying vacuum-tube ideas and procedures and while this may have been a necessary step in the transition period it is not the most fruitful method. At present, more and more use is being made of characteristics peculiar to transistors, and considerable work is being done to change the basic circuitry to agree with transistor characteristics.

CHAPTER 11

LOUD-SPEAKERS AND ROOM ACOUSTICS

By Hugh S. Knowles[1]

In the design and operation of electroacoustic devices, consideration must be given both to the physical or "objective" properties of the sounds that are to be reproduced and to the psychophysiological or "subjective" processes involved in hearing.

1. Sound is an alteration in pressure, particle displacement, or particle velocity propagated in an elastic material or the superposition of such propagated alterations.

2. Sound is also the sensation produced through the ear by the alterations described above. In case of possible confusion the term "sound wave" may be used for concept 1, and the term "sound sensation" for concept 2.[2]

In the case of a sound wave in air the pressure is alternately above and below atmospheric.

The velocity of propagation, c, of a sound wave of small amplitude is

$$c = 33{,}060 + 61\theta \qquad \text{cm/sec} \tag{1}$$

where θ is the temperature in degrees centigrade. The wavelength λ is given by the relation $\lambda = c/f$, where f is the frequency in cycles per second. The density ρ of dry air at 20°C and at a pressure of 760 mm is 0.001205 g per cc.

The intensity of a plane or spherical "free" sound wave (no reflection) in the direction of propagation is

$$I = \frac{p^2}{\rho c} = 2.42 \times 10^{-9} p^2 \qquad \text{watt/sq cm} \tag{2}$$

where p is the effective sound pressure (dynes per sq cm).

The standard reference intensity is 10^{-16} watt per sq cm. The intensity level in decibels of a plane or spherical free sound wave in the direction of propagation is

$$L_I = 10 \log_{10} (2.42 \times 10^7 p^2) \tag{3}$$

In a plane or spherical free wave the intensity is proportional to the square of the pressure. In this case the pressure level in decibels of a sound wave is defined as

$$L_p = 20 \log_{10} (p/p_0) = 74 + 20 \log_{10} p \tag{4}$$

where p_0 is the standard reference pressure of 0.0002 dyne per sq cm. Two pressures are said to differ by x db if 20 times the logarithm to the base 10 of their ratio is x. As in the analogous electrical case involving a field strength or voltage ratio, this is valid only if the impedances are identical so that the energy is proportional in both instances to the square of the respective pressures. For this reason Eq. (2), in general, does not hold in more complicated fields. On the other hand the use of Eq. (4) is justified in more complicated sound fields by the fact that the hearing sensation depends primarily on the sound pressure.

1. Speech. The variation in conversational speech power with frequency is shown in Fig. 1. The ratio of ⅛ sec peak to averaged power in 15-sec intervals is roughly

[1] Knowles Electronics, Inc.

[2] American Standard Z24.1, Acoustical Terminology.

20 db. In overloaded amplifiers such as are frequently used in public-address systems, or in intentionally peak-clipped or compression systems the ratio may range from 3 to 10 db. This ratio is important in temperature-limited loudspeakers (see Tests).

The distribution of energy with frequency is brought out differently in Fig. 2.
FIG. 1. Variation of conversational speech power with frequency. (*After Sivian and Fletcher.*)

Articulation curves which give a measure of the "recognizability" of speech are shown in Fig. 3. The percentage of called sounds correctly recognized is the per cent articulation. Tests of syllable, sound, vowel, individual sound, and other types of articulation are now widely used in the laboratory and to an increasing extent in the field to determine the suitability of a system for the transmission of speech. "Intelligibility" tests, in which the content of a simple sentence is to be understood, are also used. On the average 30 per cent syllable articulation corresponds to nearly 90 per cent "discrete sentence" intelligibility, indicating the relative ease of understanding connected speech. From Figs. 2 and 3 we note that reproducing only the frequencies above 400 cps halves the system power requirement and yet reduces the articulation by a negligible amount. In a power-limited system in which speech articulation is important, the transmission band is sometimes limited to from 600 or 800 to 4,000 cps, corresponding roughly to the 90 per cent articulation points at each end. This reduced band roughly quarters the power requirement.

FIG. 2. Speech-power variation with frequency. (*After Fletcher.*)

Articulation and naturalness are not to be confused. By successively raising the

cutoff of high-pass filters and lowering the cutoff frequencies of low-pass filters, each by a barely perceptible amount, Schäfer has shown that the required transmission band for natural speech reproduction includes some 32 to 36 minimum perceptible changes in band width.[1]

Gannett and Kenney have experimentally determined the successive reductions in the cutoff frequency of a low-pass filter required to obtain 75 per cent correct judgments by a trained jury when listening to speech and music.[2] On speech (average of male and female) the cutoff had to be lowered from the maximum available of 15 to 8 kc, then from 8 to 5 kc to produce a second reliably detectable step. On music the successive cutoffs were 11, 8, 6.5, and 5 kc.

FIG. 3. Variation of articulation with transmitted frequency range. (*After Fletcher.*)

Corresponding values for the successive increases in the cutoff frequency of a high-pass filter were calculated on less complete data. The cutoff had to be raised from 40, the lowest available, to 150 cps on speech for the first reliably detectable step. On music the first step was from 40 to 80 and the second from 80 to 150 cps.

FIG. 4. Variation with frequency of the power output of a 75-piece orchestra. (*After Fletcher.*)

From these data we conclude that, when the cutoff frequencies lie in the 40- to 150-cps and 5- to 15-kc ranges, trained listeners can detect twice as many band-width changes on music as on speech. Excellent speech can be transmitted over a 150- to 8,000-cps range and excellent music over an 80- to 11,000-cps range.

2. Music. The frequency distribution of the maximum and most probable peak powers for a 75-piece orchestra is shown in Fig. 4. The curves are based on average measurements of four selections which gave whole "spectrum" peak powers from 8 to 66 watts and average powers of 0.08 to 0.13 watt. Zero level corresponds to an average power of about 0.1 watt. As in the case of speech the

[1] Schäfer, E., The Audibility of Variations in Frequency Band in Speech Transmission, *Elek. Nach.-tech.*, **15** (8), 237, August, 1938.

[2] Gannett, D. K., and I. Kenney, The Discernibility of Changes in Program Band Width, *Bell System Tech. J.*, **23** (1), January, 1944.

average power over 15-sec intervals is about 1 per cent of the peak power in 18-sec intervals.

The power output of various musical instruments is shown in Table 1. The bass drum may radiate over a third of the peak power of a 75-piece orchestra. The large

Table 1. Peak Powers in Music

15-piece orchestra	6 ft from nearest instruments, in same room as piano. Average of 2 methods	7.9	126.0	9.0	1.5	250– 500 2,000– 2,800
75-piece orchestra	15 ft from nearest instrument in theater	4.6	129.0	66.5	1.0	250– 500 8,000–11,300
Pipe organ	Effective distance 15 ft. Radiation assumed uniform over ¼ sphere	20.0	90.0	12.6	36.0	20– 62.5

peaks in the 20- to 62.5 cps range of the organ are well known to recorders and electronic organ people who find it desirable to use l-f stops which are "rich in harmonic development" and therefore sound much louder without badly overloading the record, amplifier, and speaker. The 15-in. cymbals follow the drums and organ closely in peak power output with 9.5 watts. Their maximum peaks occur in the 8,000- to 11,300-cps range. Transmission systems having a "predistorted" frequency characteristic which includes a marked rise in h-f response in some part of the system (such as f-m and television transmitters) are frequently overloaded by this instrument. The same problem occurs in recordings recorded with a similar characteristic.
FIG. 5. Audible frequency ranges of musical instruments and sounds. (*After Snow.*)

The high output of the trombone in the 2,000- to 2,800-cps band near the frequency of maximum ear sensitivity gives the trombone (and other brass instruments) their piercing "bite." It has been found that the ear critically appraises the response of a system in this range and that surprisingly small changes can be detected. This suggests that the balance of the brasses in a studio pickup merits special attention.

The audible frequency ranges of many musical instruments are shown in Fig. 5. The vertical ruled portions indicate the frequency range in which noises accompanying the playing of the instrument occur. While the elimination of these frequencies permits the fact that the frequency range is restricted to be detected, it does not mean that the quality is judged to be best with the unrestricted range. In many cases the quality of the reproduced music from instruments which radiate extraneous noises (reed, bowing, key, and others) is improved by eliminating the noise range.

In restricting the transmitted frequency range of reproduced music, we have to be primarily concerned with the degradation in quality as judged by a good "sound jury" rather than with recognition of the selection played or the power distribution with

frequency or "spectral composition" of the music. The average results of a test of this kind, using a jury of 10 and an 18-piece orchestra, are shown in Fig. 6. Considering the many variables involved, the maximum and mean deviations from the curve were surprisingly small. It was the judgment of the observers that the quality improved rapidly as the lower range was extended down to 80 cps and the upper up to 8,000 cps.
FIG. 6. Variation in quality of reproduced orchestral music with transmitted frequency range. (*After Snow.*)

It has been found experimentally that, if the transmitted frequency range is to be restricted, good balance between low and high frequencies may be obtained by so choosing the range that approximately equal degradation in quality occurs because of loss of low and high frequencies. For reasonable degradation the product of these two frequencies is roughly 640,000. The square root of this product or the geometric mean of these frequencies is therefore roughly 800 cps. A system transmitting more octaves below 800 cps than above usually sounds "heavy," "thick," or "drummy." Likewise a system transmitting more octaves above 800 cps than below will sound "thin" or "tinny." This assumes flat response
FIG. 7. Pressure variation with frequency for two isolated damped sinusoids with different rates of decay; initial amplitudes the same in the two sets of curves.

in the range and similar cutoff characteristics. A sharp cutoff at one end will increase the apparent output at that end because of the transient response which accompanies such a cutoff. A peak in either range will increase the steady-state and transient response in that region. This can be only partly balanced by added response in the other range.

In considering the problem of reproducing sounds in a complete system including

the effect of the room at the source of sound and at the source of the reproduced sound, it is desirable to know the energy distribution with frequency of a typical sound. The importance of this will be discussed under Room Acoustics. Since a common type of sound in music is a damped sinusoid, corresponding, for example, to the sound output of a plucked string instrument, the spectral analysis for two waves with different rates of decay is shown in Fig. 7. Any isolated wave train of this type contains energy which covers an infinite frequency interval. By analogy with the optical case the spectrum is said to be a continuous or band spectrum.

The highly damped wave contains appreciable energy at frequencies differing up to from 20 to 30 per cent from the frequency of a corresponding undamped wave. As the rate of decay is decreased, the wave train contains more energy, and an increasing amount of this is concentrated near the undamped frequency of the wave. In the limit when the rate of decay is zero and the wave has existed for an infinite length of time, *i.e.*, when we have a steady state, the band spectrum degenerates into a line spectrum with all the energy concentrated at the undamped frequency of the wave.

The fact that music and speech are not of a steady-state character but vary from instant to instant (and therefore have a continuous distribution with frequency of their energy) substantially aids their satisfactory transmission in a room (see Room Acoustics).

3. Noise. Noise is an "unpitched" sound composed of a large number of discontinuous, nonperiodic sounds. Therefore the energy in noise is distributed in a continuous manner with frequency. A click, for example, closely approaches the hypothetical pulse which lasts for an infinitesimal length of time and the energy of which is continuously and uniformly distributed with frequency. A noise may have one or more broad peaks in its spectrum, but a sharp peak indicates a nearly periodic disturbance which will give the noise a definite pitch.

Table 2. Noise Levels

Pressure, dynes per sq cm	Noise level, db above reference threshold	Type of noise
630	130	Pain threshold
250	122	Airplane—1,600 rpm, 18 ft
45	109	Boiler factory
25	102	Subway train passing station
13	96	Elevated train—15 ft
4.0	86	Heavy traffic—15 ft
2.0	80	Average truck—15 ft
1.3	75	Average factory location
6.3×10^{-1}	70	Average automobile—15 ft
3.2×10^{-1}	64	Department store
1.1×10^{-1}	55	Average office
2.8×10^{-2}	43	Quiet office
6.3×10^{-3}	30	Very quiet residence
1.4×10^{-3}	17	Gentle whisper—5 ft
4.5×10^{-4}	7	Threshold (for street noise)

The properties of noises are of some importance because (1) the proper reproduction of intended noises may enhance the dramatic value of the reproduction, (2) the ambient noise levels in studios or halls and in rooms frequently limit the dynamic range at the "pickup" and "playback" points, and (3) they influence the response of the ear by producing masking or artificial deafening.

The reproduction of most noises requires the transmission of substantially the entire audible frequency range. For this reason noises are frequently used as test material in high-quality systems. The frequency ranges of footsteps, hand clapping, and key jingling are shown in Fig. 5. These indicate that it is particularly important that all the upper audible frequencies be transmitted.

The intensity level of various representative noises is listed in Table 2. In urban locations, particularly in large buildings, the ambient noise level in moderately quiet rooms is of the order of 45 to 60 db. This noise level is high enough so that even in specially treated broadcasting studios it frequently limits the dynamic range of the transmitter.

Even in relatively quiet residential sections the ambient noise level in a typical listening room is high enough so that it, too, places a lower limit on the intensity of the sound required to override the noise.

4. Hearing. All the data contained under Speech, Music, and Noise which were obtained by the use of a sound jury or listener involve the sensation produced in the listener by the designated source of sound. All tests of this type depend to some extent on the techniques employed and, of course, on the observers. All similar tests are of principal value when the jury is composed of a large selected sample with known hearing characteristics.

One of the most important properties of sound is its loudness. In the case of typical sounds and especially those in the mid-frequency range the intensity (power) must be increased by a factor of 10 to double the loudness. In high-power systems
FIG. 8. Loudness level curves showing variation in sound intensity with frequency required to produce a sound judged to be as loud as the 1,000-cps reference sound intensity given on the curves. (*After Fletcher and Munson.*) Solid curves obtained with listener facing sound source. Dashed curve indicates threshold (corresponding to solid curve 0) but for sound of random incidence. (*After Sivian.*) For more recent data on a larger sample of ears see D. W. Robinson and R. S. Dadson, A Redetermination of the Equal Loudness Relations for Pure Tones, *Brit. J. Applied Phys.*, **7**, 166–181, 1956.

the required loudness should therefore be critically evaluated. This has been found to vary with both the frequency and intensity of the sound. To a rough approximation it has been found that in the middle frequency range equal percentage increases in intensity produce equal increases in loudness. The *loudness* is the magnitude of the hearing sensation and is assumed proportional to the number of nerve impulses reaching the brain per second.

The *loudness level* contours for a sample of 200 ears are shown in Fig. 8. These curves were obtained by alternately listening to a sound of arbitrary frequency and intensity and comparing it with a 1,000-cps tone the intensity of which was adjusted until the two were judged to be equally loud. At 1,000 cps therefore the loudness level of the sound corresponds to the intensity level because this is the reference test frequency. The intensity is that which exists in an undisturbed sound field before the listener is immersed in it. The observer faces the source and listens to the sound binaurally. By plotting the differences in minimum audible field intensities for sound of normal and random incidence found by Sivian, we obtain the dashed curve in Fig. 8. This indicates that the other contours for sound of random incidence would also be more regular.

Reports have been made by Beasley on a sample of 16,000 ears. Some of the results are shown in Fig. 9. The curves show the percentage of the sample tested
FIG. 9. Threshold of hearing curves for large population sample. Percentage figures indicate percentage of sample tested having a hearing threshold lower than the corresponding curve. (*After Beasley.*)
FIG. 10. Loudness variation with frequency for three tones of the indicated intensity showing reduced loudness of low-intensity low-frequency sounds.

which had lower thresholds of hearing than the indicated value. For example, the solid curve marked 50 per cent indicates that 50 per cent of the ears tested had thresholds of hearing lower than that indicated by this curve. From these data we see that the Fletcher and Munson threshold curves are for ears in the best 1 per cent of the 16,000-ear sample, and that hearing deficiencies are prevalent enough to justify their consideration in equipment design.

The loudness or apparent response or transmission characteristic of a system emitting a plane free sound wave of three constant intensity levels is shown in Fig. 10. A sound of constant 100-db intensity level seems almost equally loud from 30 to 6,000 cps. A sound of moderate intensity (constant 60-db intensity level) is inaudible below 60 cps and increases in loudness rapidly up to 400 cps. In the presence of noise, masking would substantially reduce the loudness at low intensities. The l-f characteristic varies much more rapidly with intensity level than the high and for this reason compensated volume controls are designed to have their maximum effect at low frequencies. It should be noted that the intensity-level compensated characteristic is a purely arbitrary thing and, although it is considered superior by some, it does not correspond to our normal experience. In practice, when we go some distance from the source, the low frequencies become inaudible. When an orchestra plays at low intensity, we get the same effect.

The effect of noise on hearing is to produce artificial deafness or "masking." The nature of the apparent deafness which results depends on the energy distribution of the noise. In normal listening environments the maximum noise *intensity* occurs at low frequencies. In fairly common cases the pressure decreases by a factor of 2 as the frequency increases by the same factor (slope = 6 db per octave). The effect of moderate noise levels is to decrease articulation. If the noise level is moderate this may be largely compensated by raising the intensity level of the sound.

LOUD-SPEAKERS

A loud-speaker is a device which is actuated by electrical signal energy and radiates acoustical energy into a room or open air. The shorter term *speaker* is used when no confusion with a person addressing a microphone results.

The selection and installation of a speaker as well as its design should be guided by the problem of coupling an electrical signal source as efficiently as possible to an acoustical load. This involves the determination of the acoustical load or radiation impedance and selection of a diaphragm, motor, and means for coupling the loaded loud-speaker to an electrical signal source. The performance of the speaker is intimately dependent upon the nature of its acoustic load and should not be considered apart from it. The nature of the radiating system, and therefore the acoustic load impedance it sees, is primarily determined by space, acoustical environment, and cost factors.

5. Radiation Impedance. When a vibrating diaphragm is placed in contact with air, its impedance to motion is altered. The added impedance seen by the surfaces which emit useful sound energy may be called the *radiation impedance.* By analogy with antenna systems the resistive part is called the *radiation resistance.* The radiation reactance or reactive part is usually positive, and the corresponding apparent mass may be called the *radiation mass.* The radiation impedance seen by a diaphragm depends on its size, shape, the frequency, the acoustical environment, and the medium into which it radiates.

6. Single Piston. The average radiation impedance per unit area seen by a flat circular piston vibrating in a thin, rigid, nonabsorbent, infinite plane or baffle in air is shown in Fig. 11. When the length of the radiated sound wave λ exceeds the circumference of the piston, $2\pi R$, the radiation resistance is nearly proportional to the square of the frequency. This relation between the wavelength and piston circumference corresponds to the frequency being less than 4,310 divided by the diameter in inches. In this frequency range the piston *velocity* should vary inversely with frequency to radiate constant power since this is equal to the product of the square

of the rms velocity and the radiative resistance [see Eq. (5)]. This variation in velocity with frequency is usually obtained by placing the fundamental resonant frequency of the diaphragm and motor near the lowest frequency to be transmitted so the system has mass reactance or is "mass-controlled" in this frequency range. When the frequency exceeds twice this value, the resistance is very nearly 41.4 mechanical ohms per square centimeter and the diaphragm (real or virtual) is efficiently coupled to the air (see Sec. 11).

When the length of the radiated wave exceeds the circumference of the piston, the air increases the apparent mass of each side of the diaphragm by approximately the
FIG. 11. Radiation resistance, reactance, and mass per square centimeter of a flat, rigid piston vibrating in an infinite, rigid nonabsorbing baffle. Piston radiates into a solid angle, $\Omega = 2\pi$ steradians (hemisphere).

mass of air contained in a cylinder whose base is the piston and whose height is 0.85 times the piston radius. At high frequencies the radiation mass ("accession to inertia") and the mass reactance decrease and approach zero for infinite frequency.

7. Mutual Radiation Impedance. When a sound wave radiated from one surface of a diaphragm has access to another surface of the same diaphragm or to a surface of another diaphragm, there is said to be coupling between the surfaces. Consideration of this mutual radiation impedance is simplified by fixing attention on what occurs at each diaphragm. The motion of the diaphragm is opposed by the ("self-") radiation impedance. It is also opposed or aided by the force exerted on it by the waves generated by any other diaphragms which are coupled to it. The (complex) ratio of the force due to all other diaphragms to the velocity of the diaphragm itself is the mechanical impedance seen by the diaphragm due to the other diaphragms. This we will call the total mutual radiation impedance.

The total radiation impedance seen by a diaphragm is the sum of the self- and the

"mutual" radiation impedances. The acoustic power P_a radiated by a diaphragm is

$$P_a = (r_S + r_M)v^2 \times 10^{-7} \quad \text{watt} \tag{5}$$

where r_S = real part of self-radiation impedance (total)
r_M = real part of mutual-radiation impedance (total)
v = rms diaphragm velocity, cm per sec

Note that the velocity appears as current would in the corresponding electrical equation. The diaphragm displacement is $v/2\pi f$, where f is the frequency. The total displacement of various diaphragms required to radiate 1 watt is shown in Fig. 12. These curves clearly show the need for large diaphragms if appreciable l-f power is to be radiated.
Fig. 12. Total displacement required of diaphragm of indicated size to radiate 1 watt. Solid curves for pistons radiating into a hemisphere at low frequencies where the radiation resistance is proportional to the square of the frequency ($2\pi R/\lambda$ less than about 1.4 in Fig. 11). Dashed curves for constant radiation resistance of 41.5 mechanical ohms per square centimeter (exponential horn value well above horn cutoff frequency).

By knowing the self- and mutual radiation impedances of diaphragms mounted in a single infinite baffle, we can determine the impedance seen when other baffles are added. In Fig. 13 assume four pistons (1, 2, 3, 4) mounted in the X plane. Because of symmetry there is no net sound flux through the plane Y since for every positive vertical (z) component from pistons 3, 4 there is a negative component downward from pistons 1, 2. We may therefore introduce the rigid, thin, nonabsorbent plane or baffle Y without altering the impedance seen by any of the pistons. With Y in place we may remove pistons 3, 4, and pistons 1, 2 will continue to see the same impedance. The sound wave reflected by the plane corresponds exactly to the wave which would come from diaphragms 3, 4 and therefore the plane is said to have created "primary images" (by analogy with the optical case) of diaphragms 1, 2 which 1, 2 cannot distinguish from the real diaphragms 3, 4. Similarly the plane Z may be introduced and pistons 2, 3, 4 removed, leaving 1 looking into its original impedance. In all cases pistons of equal size, vibrating in phase and with the same amplitude in infinite, rigid, nonabsorbing baffles, are assumed. The relations hold approximately when the baffles are a wavelength or more long. Finite

impedance of a baffle may be treated by assuming reduced amplitude of the image to account for absorption and a change in phase to account for the reactive part of the impedance. The principle is readily extended to multiple sources of arbitrary size, phase, and displacement such as occur in vented enclosures, labyrinths, and the like.

Several piston combinations are shown in Fig. 14. All pistons marked with the same letter "see" the same radiation impedance. The ratio of the radiation resistance and reactance seen in each case to that seen by a single piston A is shown in Figs. 15 and 16. The actual impedance is therefore obtained by multiplying the ordinates of Fig. 15 or 16 by the corresponding ordinate of Fig. 11. The letters on the curves correspond to those on the pistons in Fig. 14.
FIG. 13. Primary images 2, 3, and 4 of piston 1 introduced by planes Y and Z.
FIG. 14. Effect of adding pistons and reflecting planes on radiation impedance. All pistons marked with the same letter see the same radiation impedance.

Values of the ordinate less than 1 indicate the piston sees less resistance or reactance than it would if alone in a single infinite plane. This occurs when the time delay in the wave from one diaphragm and the frequency are such as to give out-of-phase pressure components at the other.

Figure 15 shows that the radiation resistance is increased by the largest factor and over the greatest frequency range when each diaphragm is as close to all others as possible. At low frequencies the group then behaves as a single large piston. Figures 15 and 16 show that the radiation resistance increases much more rapidly than the reactance as speakers (or their images) are added. The exact improvement in efficiency which results depends on the impedance seen looking back into the speaker diaphragm but a typical speaker efficiency is increased by a factor of nearly 2 (3 db) for case B and 3.2 (about 5 db) for case C. This indicates qualitatively the improvement gained at low frequencies by operating a speaker at the intersection of the floor and wall and in a corner, respectively.

For a given diaphragm amplitude one speaker in locations B and C will radiate two and four times as much l-f energy, respectively, as one in location A. The radiated

power for constant amplitude is therefore proportional to the square of the number of actual diaphragms. The radiation resistance at high frequencies is not improved by the use of additional speakers. A group of speakers therefore has better low but no better and possibly less h-f response than a single one, and they therefore sound as though they had relatively less high response. Except for cost reasons multiple speakers are usually preferred to a single speaker with the same size motor because (1) the small diaphragms are lighter per unit area than a large one of adequate rigidity, giving better efficiency and high response; (2) the angle of individual speakers may be adjusted a moderate amount to give a good h-f directional pattern without injuring the l-f response; (3) reliability is improved, since failure of a single unit usually does not seriously affect the performance of the group; and (4) the temperature rise of each voice coil may be reduced.

FIG. 15. Ratio of radiation resistance seen by a piston in the presence of one or more others (real or images) vibrating with equal amplitude and phase to radiation resistance it would see alone radiating into a hemisphere. Designating letter of curve is same as that of corresponding piston in Fig. 14. (*After Klapman.*)

MULTIPLE LOUD-SPEAKERS

Some of the advantages of multiple direct-radiator speakers where these all cover the same frequency range are discussed in Sec. 7, Mutual Radiation Impedance, above. It is also shown, however, that at intermediate and high frequencies, added diaphragms may, and usually do, reduce the mutual radiation resistance. This results in dips in the response curve of the combination of speakers, which may be serious. Multiple speakers are also sometimes used to control directivity as in "line" sources in which as many as 8 or 10 are mounted in a vertical

FIG. 16. Ratio of radiation reactance (or mass) seen by a piston in the presence of one or more others (real or images) vibrating with equal amplitude and phase to reactance (or mass) it would see alone radiating into a hemisphere. Designating letter of curve is same as that of corresponding piston in Fig. 14. (*After Klapman.*)

line to reduce the vertical angle of radiation but to preserve a broad horizontal angle. Multiple-speaker systems in which the speakers cover complementary frequency ranges also have certain advantages and are widely used. The more important advantages
FIG. 17. Effect of concentration of radiation on piston axis at high frequencies for the case of pistons radiating constant *total* power (top curves) and the case of constant pressure response on the axis (lower curves). Because of cone flexing the concentration is less marked in actual diaphragms where the equivalent piston diameter at high frequencies approaches about six-tenths the actual cone diameter.

are (1) improved frequency response, since each type of unit covers a moderate range; (2) higher system efficiency, for the same reason; (3) improved directivity characteristic, since the diaphragm (or horn mouth) for the highest frequency range may be made relatively small (see Figs. 17, 18, and 19); (4) improved transient response, since many of the artifices used to obtain extended frequency ranges in single units make the transient response worse, particularly at high frequencies; (5) reduced intermodulation, since large amplitudes are confined to speakers reproducing low frequencies; and (6) reduced frequency modulation which occurs when a single diaphragm moves with large amplitude at low frequencies with respect to the listener while simultaneously radiating high frequencies, thereby altering the frequency of the high frequency because of the Doppler effect.
FIG. 18. Variation in relative response with angle up to the angle for which the first minimum occurs. The response on the axis has been arbitrarily adjusted to the same reference level in all curves.

8. Piston Directivity. With rising frequency the radiation from a rigid piston becomes increasingly concentrated on the axis, as shown in Figs. 17 and 18. Figure 17 shows that, if the flat axial pressure response curve so often sought after is obtained, the total radiation and therefore the efficiency are actually falling rapidly at high frequencies. Conversely, if a speaker is to have constant efficiency its axial pressure response must rise appreciably at high frequencies. The variation in relative response with angle up to the angle for which the first minimum occurs is shown in Fig. 18. The response on the axis has been arbitrarily adjusted to the same reference level in all curves. At high frequencies the effective area of an actual cone is reduced by flexing, so that the directivity of actual cones is somewhat less than that shown for the piston.
FIG. 19. Experimentally determined directional characteristics for one elliptical and two circular diaphragms. The elliptical diaphragm has the broadest characteristic in the *horizontal* plane when its major (long) axis is *vertical.*

Typical directional curves for 6- and 10-in. (designating size) speakers are shown in Fig. 19. The axial response is assumed equalized to give flat response and the relative response for other angles is shown. Typical directional curves for a 6- by 9-in. (designating size) elliptical speaker are also shown. These show that the directional response of this elliptical speaker in the plane of the *minor* or short axis is roughly comparable to that of a circular speaker with a diameter equal to the minor axis. The directional response in the plane of the major or long axis is worse than that of a 10-in. circular speaker up to about 6,000 cps. Above this frequency it is better. Contrary to popular belief the elliptical speaker should be mounted with its major axis *vertical* to get broadest distribution in the *horizontal* plane. This corresponds to the theoretical predictions of Stenzel. This same effect is present in rectangular mouth-shaped horns where the middle and middle h-f response is *most directional* in the plane of the *broadest* horn mouth dimension unless partitions, or separate cells, are used. Even then the effect is present when the wavelength is comparable to the smaller dimension of the entire mouth.

9. Horns. A horn is a tapered acoustical transmission line used to couple the impedance it sees, looking back into the diaphragm, as effectively as possible to the load it sees looking out of its mouth (see Motors). The small end of a horn is called its *throat,* the large end its *mouth.* If its mouth has an infinite flange or baffle, the

radiation impedance it sees is approximately the impedance given in Fig. 11. If there is no flange, the radiation resistance is half and the reactance approximately seven-tenths this value at low frequencies. At high frequencies the flange does not alter the impedance.

It has been found that many of the horns commonly used in loud-speakers belong to the hyperbolic exponential or "catenoidal" horn family, in which the cross-sectional area, A, is related to the axial distance by

$$A = A_t \left[\cosh\left(\frac{x}{x_0}\right) + T \sinh\left(\frac{x}{x_0}\right)\right]^2 \tag{6}$$

where A_t is the throat area, x_0 is a constant fixing the axial scale of length, T is a constant determining a member of the general family, and the cosh and sinh are the hyperbolic exponential cosine and sine functions, respectively. The longitudinal sections of these horns for various values of T are shown in Fig. 20 for straight-axis circular horns.

Fig. 20. Longitudinal section of straight-axis circular cross-sectional horns of hyperbolic exponential or catenoidal family.

When T is infinite, a conical horn is obtained. For T equal to unity the bracketed expression reduces to e^{2x/x_0}, yielding the equation for the familiar exponential horn. At T equal to zero the shape is that of the hyperbolic cosine, with zero slope at the origin.

The performance of a horn depends principally on the throat impedance and its dependence on frequency. While waves reflected from the mouth introduce fluctuations into the throat impedance, it has been found that the average impedance is closely that of a horn with no reflected wave. The throat impedance in mechanical ohms of catenoidal horns with rigid, nonabsorbent walls and negligible reflected waves is given by

$$Z_t = R_t + jx_t = A_t\rho c \frac{[1 - (f_c/f)^2]^{1/2} + j(Tf_c/f)}{1 - (1 - T^2)(f_c/f)^2} \tag{7}$$

where ρ, c, and T have been defined, f is a frequency, and f_c is the cutoff frequency, given by $f_c = c/2\pi x_0$. Thus the reference axial length x_0 is of fundamental importance in determining the behavior of the impedance. In Fig. 21 is shown the behavior of R_t for various values of T. The product ρc has been replaced by 41.4, its value in cgs units at room temperature.

Fig. 21. Frequency dependence of throat resistance for horns of various values of T. Below f_c the resistance is zero.

For frequencies below f_c the resistance R_t becomes zero, and the horn cannot lose energy to the medium. In practice there is a slight amount of radiation below this, so that the transition is not too abrupt. In many designs the cutoff of the system comprising amplifier, horn-driver unit, and horn may be judged aurally to be 10 or 20 per cent above the theoretical horn value because of impedance effects arising from other elements of the system (see Motors).

The behavior of the horn throat impedance is conveniently expressed by an equivalent electrical circuit of the mechanical elements, as in Fig. 22. The constant mass, m_t, depends inversely on T and is shunted

by the frequency-dependent resistance, R_t. These two elements account for the high-pass characteristic of horns. The driver unit is coupled to the horn by the sound chamber, which has a volume, V_c, terminated by the horn-throat area, A_t, and by the diaphragm area, A_d. This acoustic element may be represented by S_c, the shunt stiffness of the enclosed air plus an ideal transformer of turns ratio A_d/A_t. Referring again to Fig. 22 the diaphragm mass and stiffness, m_d and s_d, are driven by a source of force with internal impedance R_0 mechanical ohms. It is this "generator resistance" to which the horn must be properly coupled to attain a speaker of high efficiency.

The reactive elements in the equivalent circuit can be chosen on the basis of filter theory, but the response so obtained may not be the type desired. In general, the ratio A_d/A_t may be chosen so as to produce approximate equality of source and load resistances in the "pass" or transmission band. In this case the resonant frequencies
FIG. 22. Equivalent electrical circuit of mechanical elements of horn speaker. The generator impedance R_0 increases with the efficiency of the speaker.

of the diaphragm alone, and of the stiffness s_c with the mass $(A_d/A_t)^2m_t$, are placed so as to emphasize the desired frequency regions.

An important horn design parameter is the cutoff frequency, which must be properly related to the resonant frequency of the diaphragm to produce the desired l-f response. Once a motor and diaphragm have been selected, the horn throat area is usually fixed by the resistance-matching consideration mentioned, and T is chosen from Fig. 21. Thus the desired horn contour may be plotted from Eq. (7) and continued until the mouth is sufficiently large to minimize reflection. This occurs at a mouth diameter greater than about $\lambda/3$ at the low cutoff frequency. An equivalent statement is that the product of the cutoff frequency and the mouth diameter (in inches) is greater than 4,500. This product can be considerably reduced if the speaker is operated under matched resistance conditions with the mechanical source resistance R_0 equal to the mechanical resistance of the loaded diaphragm loaded by the horn for then a 4:1 change in load resistance results in but a 2-db reduction in output. This can be attained, over a broad frequency band, only with a very efficient motor. Thus the irregularities due to wave reflections at both ends of the horn do not show up strongly in the radiated energy.

The dimensions of the sound chamber are fixed by considerations of distortion and h-f cutoff. If the motion of the diaphragm is comparable to the clearances, then the stiffness, s_c, will vary throughout the cycle and lead to intermodulation distortion. However, if the clearance is increased, the value of s_c is lowered, hence its reciprocal, the capacitance, raised, thus shunting the horn load excessively at high frequencies. To calculate the amplitude of diaphragm motion there may be used the expression for the radiated power

$$P_a = 10^{-7}(\omega y_d)^2 A_d^2 \frac{R_t}{A_t} \tag{8}$$

evaluated about an octave above the cutoff frequency. Here P_a is the acoustic power in watts, and y_d the diaphragm amplitude in centimeters. Note that frequency enters into both ω and R_t.

At high frequencies such that the wavelength is comparable to the diaphragm diameter, transverse waves in the sound chamber produce cancellation effects which sharply reduce the radiated power. This condition can be ameliorated by subdivision of the throat into properly placed annular slots, as in Fig. 23, or by an annular diaphragm, as in Fig. 24. In these structures the sound chamber stiffness, s_c, may be considered a lumped constant equal to $1.37 \times 10^6 A_d/V_c$ dynes per cm over most of the frequency range, where A_d and V_c are defined above. The capacitance is the reciprocal of this value.

Fig. 23. Cross section of annular V-shaped diaphragm and sound chamber used to reduce destructive interference in sound chamber at high frequencies.

The cross-sectional area of exponential horns varies exponentially with length. Thus a horn with a 70-cycle cutoff doubles in throat area every 11 in. along the axis, and the area of a 100-cycle horn increases 20 per cent every 2 in.

With a horn the directionality of the speaker may be controlled almost independently of the response, because the directional properties are fixed mainly by the mouth size and shape. Thus it is possible to obtain in horn speakers more control over response, efficiency, and directivity than in direct-radiator types.

Fig. 24. Cross section of a diaphragm and sound chamber in which annular slots are used to reduce destructive sound-chamber interference at high frequencies.

DIAPHRAGMS

10. Principle of Operation. The diaphragm is the part of the speaker which couples the radiation impedance to the speaker motor impedance. In the usual hornless or direct-radiator speaker, the force exerted by the motor is localized, and this must be transmitted to the acoustic load which is spread over a large area. To do this effectively and to add as little as possible to the impedance, the diaphragm is made as rigid and light as possible. Conical shaped diaphragms are commonly used because they are rigid. The term "cone" is frequently used as a synonym for diaphragm in direct-radiator speakers.

The usual conical diaphragm may be thought of as a continuous mechanical transmission line radiating acoustic energy from each element of area. There exist both radial waves which travel from the driven region to the edge and are reflected, and circumferential waves which travel around the diaphragm. Both occur in various combinations depending on the mode of vibration and the symmetry of the driving force, diaphragm, and supporting members.

The lowest frequency mode and the simplest ane is the one in which the effective radial wavelength of the diaphragm, including the edge termination, is $\lambda/4$. (This must not be confused with a $\lambda/4$ in air at the same frequency.) At this frequency, which ranges from 700 cps in large to 1,400 cps or more in small conical diaphragms, no circumferential wave is present, and all parts of the cone move in phase. The

displacement is a maximum at the apex and a minimum at the flexible annulus which supports the outer edge and terminates the transmission line. The impedance of this termination plays an important part in the diaphragm behavior, especially at frequencies near the fundamental resonance of the diaphragm and motor and in the 1,000- to 2,000-cps range. At the l-f resonant frequency it may be considered a lumped stiffness whereas at the h-f end its distributed mass and stiffness are important.

At frequencies below the lowest mode of the cone itself all parts of the cone move in phase, and the cone behaves approximately as a piston unless the annulus stiffness increases rapidly with displacement, in which case the cone may flex at even very low frequencies. The annulus is frequently made this way deliberately in inexpensive speakers to produce l-f distortion and substantially increase their loudness by radiating most of the energy at harmonic frequencies. Unfortunately, intermodulation of low and high frequencies then also occurs, which makes the high end sound rough or garbled when a strong low note is reproduced.

11. Size. It has been found experimentally that at low frequencies the effective area of the cone is its projected or base area. This is approximately the "cone" size where this is defined for a circular cone as "the diameter to the nearest ¼ in. of the minimum circle determined by the tangency of the cone and a plane touching its base."[1] This is not to be confused with the *designating* size of a loud-speaker which is commonly used in describing a speaker.

> The designating size of a loud-speaker employing a circular radiator shall be twice the maximum radial dimension, measured to the nearest eighth-inch, of the front of the speaker except that the designating size shall not exceed the maximum diameter of the unsupported portion of the vibrating system by more than 25 per cent.[2]

This definition is intended to limit the amount of functionally useless cone housing included in the designating size. Representative cone sizes for various speaker-designating sizes are shown in Fig. 12.

FIG. 25. System efficiency of four speakers using identical moving-coil motors but different cone sizes (calculated). Designating size of speaker is given.

In direct radiator speakers and at low frequencies the radiation resistance is proportional to the fourth power of the radius (square of the area) and the reactance to the cube of the radius. The resistance-reactance ratio or power factor of the radiation impedance is therefore proportional to the piston radius. For constant radiated power, at a constant low frequency, the piston displacement varies inversely with area. With fixed amplitude the radiated power is proportional to the square of the area at a given frequency, or equal power may be radiated at half the frequency if the area is increased by a factor of 4. The upper limit to diaphragm size is set by the increased mass *per unit area* required to get a sufficiently rigid structure. The nature of the acoustic load (horn, enclosure, cabinet, etc.), space limitations, cost, and the motor employed also control size.

It is customary to increase the size of the motor as the diaphragm size is increased, since the mechanical impedance looking back into the motor (voice coil, say) should go up as the impedance looking into the driving point of the cone rises to maintain

[1] EIA, definition M5-111.
[2] EIA, definition M5-110.

good energy transfer. If a large cone is put on a small motor, the displacement and distortion for a given acoustic output drop and lower frequencies may be reproduced with the same distortion, but the efficiency in the mid-range may actually drop. These effects are illustrated in Fig. 25, in which the calculated system efficiency of four speakers using different size cones but the same motor is shown. Minimum cone masses, found to be satisfactory experimentally, and average mechanical resistance and resonant frequencies were assumed. The motor is an intermediate size normally employed on 8-in. speakers but frequently used on all four diaphragm sizes. Speaker efficiency, even at low frequencies, is therefore not limited by cone size. The cone size must be large, however, if appreciable power is to be radiated with reasonable cone excursions at low frequencies.

12. Shape. The most efficient shape at low frequencies is circular. This is also the most satisfactory structurally. Theoretical and experimental investigations have shown that an ellipse with a major to minor axis ratio of two and a two-to-one rectangle have an average of 5 and 7 per cent lower radiation resistance in the useful l-f range than a circle of the same area. The loss is progressively greater as the shape departs still further from circular. In spite of the visual appeal of elliptical and other diaphragm shapes, their fabrication and structural disadvantages have prevented their general adoption.

At high frequencies all pistons have the same radiation resistance per unit area, but most cones cannot be considered pistons, both because they are not flat and because their radial length exceeds $\pi/4$ and flexing is therefore important.

The shape of the cross section or profile of the diaphragm depends on the application and response desired. Straight side cones without corrugations are usually employed when high total radiation in the 2,000- to 5,000-cps range is required and when reproduction above 6,000 to 7,000 cycles may actually be undesirable. This is frequently the requirement of outdoor public-address and phonograph systems where noise and distortion are otherwise objectionable. Curved cones improve the response above 6,000 to 7,000 cps by providing a diaphragm impedance, viewed from the voice coil, which has a more uniformly high negative reactance and therefore absorbs more power from the high positive reactance (due to the voice-coil mass) seen looking back into the voice coil. This improvement is obtained at the expense of 2,000- to 5,000-cps response and with a weaker cone structure, with the result that straight cones are more commonly used.

13. Material. Hard, impregnated or filled, and pressed or calendered papers are used when loudness efficiency and apparent h-f response are important. Radiation resistance provides very little dissipation in direct radiator cones; hence, by using a paper having low internal flexural losses, the conical transmission line is made to have strong resonances. Many direct radiator speakers now use material of this type. The transient response of diaphragms of this type is necessarily poor since noncenter moving modes of the cone are inappreciably damped by the motor. Soft, loosely packed, or felted blotterlike cones are used when some loss in h-f response can be tolerated and a smoother response curve with reduced transient distortion is required. The loudness efficiency of high-loss cones of this type is several decibels lower than that of low-loss cones.

Felt, leather, rubber, and similar materials have been used as the annulus to terminate the conical transmission line in a low-stiffness high-resistance material. Their effect is to add considerable dissipation to the cone at the termination, resulting in reduced reflection of the flexural wave. The effect is similar to that obtained in soft cone materials, where, however, the dissipation is distributed along the line. These materials are now used infrequently because they increase the cost, lower the loudness efficiency, and necessitate larger air-gap clearances than are used when the annulus is made an integral part of the diaphragm. A more common method is to coat the paper annulus heavily with a plastic having high dissipation.

14. Breakup Subharmonics. The term *cone breakup* is sometimes applied to the flexing or wave-transmission process in a cone. Since there is nothing discontinuous

in the process to suggest the word "break" and to avoid ambiguity, it is suggested that this term be applied only in the other sense in which it is used, to name the process which results in the generation of subharmonics.

If the apex of a cone is driven with an adequate sinusoidal force at certain critical frequencies, the radiated wave contains not only the fundamental and integral multiples (harmonics) of it but also a frequency corresponding to half (and rarely to a quarter) that of the fundamental and integral multiples of this subharmonic. While distortion in the motor may contribute to this, some unpublished research has shown that the cone is the important source.

FIG. 26. Variation in radiated distortion products with voice-coil current showing abrupt start of half frequency (subharmonic) and odd multiples of it. Subscript indicates factor by which fundamental frequency is multiplied to obtain frequency of indicated distortion product.

The half frequency appears very suddenly at a critical input as shown in Fig. 26. To simplify the graph, the fundamental and usual harmonics, which would include even multiples of the subharmonics, are not included. From the total (rms) harmonic curve H_Σ, which includes these unplotted terms, we see that negligible rise in total distortion occurs when the subharmonic begins. The ear, however, reports a large increase because the pitch sense of the output has dropped an octave and the distortion has a high annoyance or objectionability factor. This type of distortion is not so important as is frequently supposed, however, because (1) it occurs only in limited frequency regions; (2) it does not occur below a moderate, critical level; (3) the time required to start it is large unless the force is large; (4) the energy distribution of speech and music is such that the probability of its production is small. Because of the statistical improbability of its frequent occurrence, it would be uneconomical to design most systems to avoid completely this occasional distortion.

MOTORS

A loud-speaker motor converts electrical into mechanical energy and couples the electrical signal source as efficiently as possible to the mechanical impedance seen looking into the diaphragm which it drives.

15. Force Factor. The mechanical circuit of a speaker motor experiences a force when a current is applied to the electrical terminals. The (complex) ratio of this force when the mechanical circuit is blocked (infinite impedance) to the current which produces it is the force factor. Since force is analogous to voltage (in the most com-

monly used system of analogues), the force factor is analogous to mutual impedance between two electrical circuits. It differs from the conventional electrical mutual impedance in that it makes no contribution to the electrical impedance when the mechanical circuit is blocked (secondary open-circuited) because its counter emf is due only to motion of the mechanical circuit, and in that the force factor in magnetic systems has opposite signs when viewed from the electrical and mechanical circuits. In usual circuit notation $z_{12} = -z_{21}$ ("antireciprocal" and not $z_{12} = z_{21}$ as in the electrical case). Since only the product of the force factors looking in both directions is involved in the following equations this will be called M^2.
FIG. 27. Magnitude of normal input impedance of various speakers all adjusted to same value at 400 cycles to simplify comparison. Magnitude of reactance of pure capacitance and inductance shown for comparison.

The normal impedance of a speaker is defined as the impedance measured or seen at its signal terminals when operating normally with its proper acoustic load. The normal impedance z_N of moving-coil and magnetic-armature speakers is

$$z_N = z_e + \frac{M^2}{z_m} \tag{9}$$

where z_e = blocked electrical impedance of the speaker
z_m = total mechanical impedance seen by the mechanical circuit including diaphragm and acoustic load

In moving-coil speakers $M^2 = B^2l^2$, where B is the average radial flux density which the coil embraces and l is the conductor length. In balanced magnetic-armature

speakers $M^2 = 4B_0^2N^2/R^2$, where B_0 is the steady flux density in the gaps, N is the number of turns on the voice (armature) coil, and R is the effective reluctance of the alternating flux path (see Magnetic Armature).

In two-electrode electrostatic speakers

$$M^2 = -\left(\frac{E_0}{\omega d_0}\right)^2 \tag{10}$$

where E_0 = bias voltage (d.c.)
d_0 = biased electrode separation
$\omega = 2\pi f$

A two-terminal load impedance absorbs maximum power from a two-terminal source when the impedance of the load is the conjugate of the impedance measured or "seen" at the source terminals. The conjugate impedance is one having the same resistive or real part and a reactive or imaginary part equal in magnitude but opposite in sign. This holds for acoustical and mechanical circuits as well, but in these the terminals are not always so readily determined.

The speaker motor therefore absorbs maximum energy from the source, regardless of the complexity of the source network, when its normal impedance is the conjugate of the source impedance. The usual source is a vacuum tube or transistor amplifier which is approximately resistive. From Fig. 27 we see that the best match is a moving-coil or "dynamic" speaker.

FIG. 28. Sectional view of small moving-coil speaker showing structural simplicity.

16. Magnetic Motors. By the IRE definition, "a magnetic speaker is a loud speaker in which the mechanical forces result from magnetic reactions." This includes both moving-conductor or moving-coil (dynamic) and magnetic-armature speakers.

17. Moving Coil. A moving-coil motor is one in which the mechanical forces result from magnetic reactions between the field of the moving coil and the applied steady radial field in the air gap. A section of half of a moving-coil speaker is shown in Fig. 28.

Moving-coil motors are very widely used because (1) their electrical impedance permits good energy transfer from the source, (2) the large amplitudes required by the popular direct radiator diaphragms are obtained conveniently with minimum nonlinear distortion, (3) the mechanical impedance of the moving element may be made low, (4) the structure is simple and rugged mechanically, and (5) the cost is low.

The impedance seen at its electrical terminals when the coil is rigidly blocked is called the *blocked impedance* of the motor or speaker. This is approximately a high resistance and low inductance in series (R_e and L_e in Fig. 29) and is therefore easily coupled to an electronic amplifier. Near the fundamental resonance of the speaker the impedance rises, and, if a low-impedance source is used, the mismatch reduces the energy absorbed.

Moving-coil speakers are sometimes called *electrodynamic* or briefly *dynamic* speakers. Both terms have been applied for many years to speakers having either electromagnet ("energized") or permanent magnet fields. The prefix "electro" in electrodynamic has nothing to do with the source of steady flux in the gap.

18. Permanent and Electromagnets. Magnetic speakers require a source of magnetomotive force to provide the steady flux. If the current source is hum-free and
Fig. 29. Equivalent low-frequency electrical circuit of moving-coil or magnetic-armature speaker in a total enclosure or in an infinite baffle. In the latter case the enclosure stiffness S_a is zero and its equivalent electrical inductance infinite.
Fig. 30. Reduced voice-coil temperature rise in permanent-magnet speakers compared to energized types. Abnormal voice-coil temperature rise when rated complex-wave input is applied at 400 cycles also shown.

therefore the flux absolutely steady, the voice coil cannot distinguish between given flux densities due to permanent and electromagnets. The efficiency of any electromagnet speaker can be equaled or excelled by a permanent magnet if cost is neglected. In small motors the permanent-magnet type is usually less expensive. In intermediate-size motors the cost of the two types is comparable if the cost of a source of field power is included. In larger motors the permanent-magnet type may be more expensive though this is largely offset by the saving in power-supply cost. In

extensive speaker systems the installed cost of permanent-magnet types is frequently lower because of simplified low-cost wiring.

Permanent-magnet speakers are very widely used particularly when a special field current supply must otherwise be provided. The temperature of the electromagnet and consequently that of the voice coil rise with time as shown in Fig. 30. The field coil resistance rises, lowering the field current and flux density. The higher voice-coil resistance and reduced flux reduce the speaker efficiency. The higher voice-coil temperature reduces the permissible signal input power in voice-coil temperature-limited speakers.

The temperature rise when the rated complex-wave input is applied at a single frequency (400 cps) in a typical intermediate-size radio speaker is also shown. The single-frequency rating is normally much less than the "complex-wave" (speech and music) rating since in the latter case advantage is taken of the high ratio of peak to average power (normally 10 to 20 db; see Secs. 1, 2, 38).

19. Magnetic Armature. "A magnetic armature speaker (or motor) is a magnetic speaker (or motor) whose operation involves the vibration of the ferromagnetic circuit." The shorter term "magnetic" may be used where no confusion will result with moving-conductor or moving-coil speakers, which are also by definition magnetic speakers. A cross-sectional view of a balanced armature motor of this type is shown in Fig. 31. Flux increases in one pair of pole faces and decreases in the other pair, when current flows through the voice coil and when the armature moves, resulting in operation analogous to a push-pull circuit. The "voice" coil does not move and therefore is made relatively large. The resulting high inductance plus distributed capacitance in high-impedance types accounts for the large rise in impedance at high frequencies (see Fig. 27). This makes it difficult to couple it to an amplifier properly. To get high efficiency the armature pole-piece clearance must be small, and this leads to limited armature displacement and possible instability.

Fig. 31. Sectional view of balanced magnetic-armature speaker.

20. Electrostatic (Condenser) Speaker. An electrostatic (condenser) speaker (or motor) is a speaker (or motor) in which the mechanical forces result from electrostatic reactions. Structurally they are capacitors in which one electrode is free to move and serve as a diaphragm. There are two-electrode or "single-ended" and three-electrode or "push-pull" types. A d-c bias potential is applied between the moving and fixed electrodes to increase sensitivity and minimize distortion. The a-c potential is superimposed on the d.c. resulting in an alternating force on the diaphragm.

Some advantages of the electrostatic speaker are: (1) the diaphragm can be very light; (2) the force may be distributed uniformly or nonuniformly over the diaphragm; (3) this force distribution may be made frequency-dependent to control the directivity at different frequencies; (4) the transient and phase distortion may be kept low by proper design; (5) the cost may be low. Some of the disadvantages are: (1) the permissible diaphragm amplitude is normally low since, to attain reasonable efficiency, the electrode spacing cannot be large (at least without high bias potentials); this leads to large-area diaphragms or limits the low cutoff frequency; (2) large-area diaphragms tend to have poor directional properties and are normally either curved or warped to improve the directional properties, with consequent structural complications, or have the effective area modified by supplying potential to zones or areas on the diaphragm in a frequency-dependent manner by suitable

networks; (3) the blocked impedance is that of a capacitor (see Fig. 27) and even with the added motional impedance is difficult to match properly except in a limited frequency range; (4) a bias potential, which is normally substantially in excess of the a-c signal potential, must be supplied; (5) because of the high potentials dielectric problems are involved.

Two-electrode types with a flat circular diaphragm, a closely spaced rear electrode, and vents to control the impedance of the thin air film have been used for some time, largely in Europe, as inexpensive tweeters. Typical types have diaphragm diameters of 3.5 to 4 in. and a low-frequency cutoff of 3 to 4 kc. The upper
FIG. 32. Simplified cross-sectional view of a two-electrode electrostatic speaker of the type used to obtain an approximately cylindrical wave front at high frequencies.

cutoff may exceed 15 kc. Laboratory types are used up to 200 kc. For ultrasonic use, machining irregularities in the fixed electrode may leave sufficient air film to provide the high stiffness and yet the diaphragm displacement needed. Where a large-area h-f speaker (tweeter) is wanted without excessive beam concentration the construction shown in Fig. 32 or a group of rectangular elements may be used in a curved array.

To increase the permissible diaphragm amplitude with acceptable distortion and hence either increase the permissible power output or lower the low cutoff frequency, three-electrode push-pull or "double-ended" types are used. A schematic diagram of this type is shown in Fig. 33. When the impedance in series with the movable electrode is made high enough so that substantially uniform charge remains on the electrode throughout the a-c cycle, the permissible amplitude is markedly increased. The marked improvement which results has been investigated analytically and experimentally by Hunt.[1]
FIG. 33. Diagrammatic representation of a push-pull electrostatic speaker. If the impedance of the d-c bias source is very high, "constant-charge" low-distortion operation is obtained.

21. Crystal Speaker. "A crystal speaker (or motor) is a speaker (or motor) in which the mechanical forces result from the deformation of a crystal having converse piezoelectric properties." The crystal has a high mechanical impedance viewed from the driving point. Only a small displacement is possible without distortion or crystal fracture, so a mechanical transformer or lever arm is used when moderate excursions are required. This leads to mechanical complications, particularly at high frequencies where the transformer is not ideal, and to added cost. The application of this type has therefore been largely limited to h-f speakers in which the diaphragm amplitude is small. The blocked impedance is that of a leaky capacitance. The normal impedance of an 8-in. unit is given in Fig. 27.

[1] Hunt, F. V., "Electroacoustics," Wiley, 1954.

COMPLETE LOUD-SPEAKERS

The more important characteristics of a complete speaker system, which includes an electrical source of known impedance, one or more speaker units (combined motor and diaphragm), any dividing networks (filters), and specified acoustic load, are its pressure response, efficiency-frequency, impedance, directional, and distortion characteristics (see Tests).

22. Pressure Response. The pressure response may be defined as the sound pressure, in dynes per square centimeter, at a designated point in the medium with respect to the speaker, per volt input. This quantity is very useful when the speaker is to be operated from a very low impedance or constant-voltage source and listened to outdoors at the same point since these conditions correspond to the test conditions. If the source (amplifier) voltage is not constant, the source is connected to the speaker, under normal use conditions, and the speaker input voltage vs. frequency is determined as the frequency is varied either by applying a constant input voltage to the amplifier or, for a complete system, by applying constant sound pressure to the input microphone.

If the speaker is reasonably free of nonlinear distortion the sum of this curve and a pressure response vs. frequency curve for the speaker will give the combined amplifier speaker frequency response.

23. Reference Pressure Response. A definition of this term which has been proposed by the IRE and ASA follows: "The reference pressure response of a loudspeaker at a specified frequency expressed in db is the difference between the output sound pressure level in a free field on the principal axis referred to a (*i.e.*, computed for a) distance of one meter, and the input electrical power level delivered to the loudspeaker rating impedance." "The rating impedance is the value of a pure resistance which is to be substituted for the loudspeaker when setting the electric power supplied by the source." The rating impedance is specified by the speaker manufacturer and is the value he decides gives the best average "match" to the source when the conflicting factors of distortion, frequency response, etc., are considered. The reference levels are 0.0002 dyne per sq cm (microbars) for pressure p_0 and 1 mw for electrical power P_0. That is, the reference pressure response G_L is given by

$$G_L = L_L - L_E = 20 \log_{10} \frac{p_L}{p_0} - 10 \log_{10} \frac{P_E}{P_0} \tag{11}$$

This penalizes the speaker if its electrical input impedance differs from the "rating impedance," which is really a rating resistance.

24. Efficiency-frequency Characteristic. The energy efficiency, or simply efficiency, of a loud-speaker is the ratio of the useful acoustic-energy output to the signal-energy input. A definition for the "rated efficiency" G_{LE} proposed by the IRE and ASA is

$$G_{LE} = 10 \log_{10} \frac{P_L}{P_E} \tag{12}$$

where P_L is the total radiated acoustic power in watts, P_E is the electric power delivered to the "loud-speaker rating impedance" in watts, and

$$P_E = \frac{E_G^2 R_{LR}}{(R_{LG} + R_{LR})^2} \tag{13}$$

where E_G is the generator (amplifier or source) voltage in volts, R_{LR} is the loud-speaker rating impedance (resistance) in ohms, and R_{LG} is the "loud-speaker measurement source impedance" (resistance) in ohms defined as "the value of a pure resistance to be connected in series with the speaker and a constant voltage source in order to measure the speaker performance."

The rated (sometimes called the "available power" or "system") efficiency penalizes the speaker if its electrical input impedance differs from the "measurement

source resistance" R_{LG}. The rated efficiency and the efficiency (conventional or "energy") as defined above may differ by a factor of 10 or more in a direct radiator speaker at the low fundamental resonant frequency if the force factor is high and the mechanical resistance low since in this case the l-f peak in the impedance may be much higher than shown in Fig. 27.

If the effective internal resistance of the source or "measurement source impedance" R_{LG} equals the loud-speaker rating impedance R_{LR}, then the rated efficiency is alternatively given in terms of the speaker parameters by

$$G_{LE} = \left| \frac{4R_{LR}M^2r_r}{[z_e + (M^2/z_m)]^2 z_m^2} \right| 100\% \tag{14}$$

where z_e = blocked voice-coil impedance plus r_s
z_m = total mechanical impedance of the mechanical mesh including diaphragm radiation and air load
r_r = total radiation resistance seen by diaphragm
M is defined under Force Factor. The vertical lines indicate that the absolute value is to be taken.

In a direct-radiator moving-coil loud-speaker mounted in an infinite baffle the rated efficiency is not constant with frequency. However, there is one region, the piston range, in which a fortuitous combination of characteristics yields a reasonably constant efficiency. For the ordinary large direct-radiator speaker this usually occurs over a substantial portion of the 100- to 800-cps range. In smaller sizes this range may be limited to 400 to 1,000 cps. Here most cones vibrate as rigid pistons, so that their radiation is closely that of a piston of the same projected area. Next, $2\pi R/\lambda$ is less than unity, so that the radiation resistance r_r varies with the square of the frequency (see Fig. 11). The frequency at which the motor is resonant usually lies well below that at which $2\pi R/\lambda$ is unity, and since the diaphragm is pistonlike, the mechanical reactance in the piston range is predominantly masslike. Also, the impedance of the voice coil is largely resistive and nearly constant. If it is coupled to a source of equal resistance and if radiation from only one side of the diaphragm is considered, it turns out that the piston-range system efficiency is equal to about $5 \times 10^{-11}\alpha E d^4/m^2$. Here α is the ratio of the volume of the voice-coil conductor (assumed to be copper) to the total gap volume, E is the magnetic energy in the gap, in ergs, d is the effective diameter of the diaphragm, in centimeters, and m is the sum of the mechanical and air masses of the moving system, in grams. From this expression it is seen that the contribution of the magnetic structure to the speaker efficiency is in terms of the gap energy, rather than the flux density or the total flux in the gap. Since the gap energy is roughly proportional to the magnet weight or the field-coil copper weight, it is seen that economic factors play a large part in determining the efficiency, at least in the piston range.

The 400-cps rated efficiency of the speakers commonly used in radio receivers ranges from 1 to 4 per cent. The corresponding 400-cps efficiency of direct-radiator speakers with very large motors ranges from 5 to 20 per cent. The rated efficiency near the low resonant frequency will be substantially less because of the poor impedance match to the source. Efficiencies of this order are more readily obtained in horn speakers, but 30 per cent is rarely exceeded over an extended frequency range. Although higher values are frequently claimed, these values, if based on any measurements, are usually based on motional impedance measurements in which all horn, diaphragm, air, eddy-current, and hysteresis losses have been assumed to be useful acoustic radiation.

25. Baffles, Enclosures, and Cabinets. "A baffle is a partition which may be used with an acoustic radiator to increase the effective length of the acoustic transmission path between front and back of the radiator." This term is usually reserved for a relatively flat baffle in which both sides of the diaphragm look into substantially a hemisphere (solid angle of 2π steradians). The term *directional baffle* is sometimes

applied when one side of the diaphragm looks into a smaller solid angle. The baffle then begins to take on the properties of a horn. There is no sharp line of demarcation, but there appears to be little reason for calling any structure which restricts the solid angle to less than $\pi/2$ (an octant of a sphere) anything but a horn.

If a baffle is used outdoors, appreciable destructive interference or pressure cancellation between the front and back waves of the speaker may occur at the listener's position at some frequency above the cutoff frequency. The frequency at which this occurs depends on the baffle size and listener location. Destructive interference at the cone itself is usually unimportant except near the cutoff frequency of the baffle. To distribute this effect and make it cover a broad band, baffles shaped as shown in Fig. 34 are sometimes used. Since the major effect depends primarily on the listener's location and a lack of reflected waves, no such simple result occurs indoors and a space average of the pressure in a moderate-size listening room shows no such effect. Conventional rectangular baffles may therefore be used indoors unless the room approaches free-field or outdoor characteristics.

FIG. 34. Irregular baffle shapes used outdoors to broaden frequency band of destructive interference between speaker front and back waves at listener's position.

The equivalent l-f electrical circuit of a moving-coil or magnetic-armature speaker in an infinite baffle is shown in Fig. 29. Here R_e and L_e are the blocked voice-coil resistance and inductance. Z_D is the electrical equivalent of the diaphragm less air load. Z_A is the equivalent of the air load, except that in this case there is no stiffness S_a provided by the air load, so its equivalent inductance M^2/S_a is infinite. M is defined in Sec. 15. S_d, m_d, and r_d are the effective diaphragm stiffness, mass, and resistance, respectively, and r_a and m_a are the radiation resistance and mass which may be determined from Fig. 11. Note that both sides of the diaphragm have radiation resistance and mass in this case and the values *per unit area* given in Fig. 11 must be multiplied by twice the piston area to give the r_a and m_a used in Fig. 29.

The magnitude of the impedance of a moving-coil speaker in an infinite baffle is shown in Fig. 27. The antiresonant impedance of the parallel circuit corresponds to the resonant frequency of the diaphragm and air load and is limited by the parallel value of the two resistances. These resistances are proportional to the square of the flux density and inversely proportional to the diaphragm and air (radiation plus dissipation) resistances. A high resonant impedance is therefore not necessarily undesirable, as is generally supposed, since it may be due to a high flux density and therefore mean a high efficiency over a wide frequency band.

FIG. 35. One type of vented enclosure in which port area is large and placed near diaphragm to obtain maximum aid from mutual radiation resistance between diaphragm and port. Phase shift of backside radiation is obtained by choice of circuit constants.

The effect of the source impedance, connected to the input terminals, on response may be noted from this circuit. If the source resistance R_{LG} is low, the speaker will absorb very little power at resonance and the acoustic output may not rise appreciably. The voice-coil resistance R_e and the source resistance R_{LG} in series are effectively across the antiresonant circuit at low frequencies since the reactance of L_e can be neglected. When the flux density is high, the Q of the antiresonant circuit alone is high but the

source and voice-coil resistances then provide substantial shunt resistance and "electromagnetic damping." The effect of this on the speaker response to a pulse is shown in the experimentally determined curves of Fig. 50. The minor irregularities in these damped sinusoids are due to h-f modes of vibration of the diaphragm. As the source resistance is raised, relatively more power is supplied the speaker at antiresonance and at high frequencies where the effect of the voice-coil inductance is important and less is supplied in the mid-frequency range. The steady-state response of a vented enclosure (see Figs. 35, 36, 37) as the source resistance or "impedance match" is changed is shown in Fig. 49. Here the response at 400 cps has arbitrarily been adjusted to the same value as the source resistance was changed.

Fig. 36. Equivalent low-frequency electric circuit of moving-coil or magnetic-armature speaker in vented enclosure.

26. Total Enclosure. A total enclosure which prevents radiation from the back side of a diaphragm may be used to prevent destructive interference between the front and back waves from a diaphragm. This might be obtained by closing the vent or port in Fig. 35. When the wavelength exceeds four times the maximum enclosure dimension, the enclosure adds a *total* stiffness S_a viewed from the diaphragm, $S_a = \rho c^2 A_d^2 / V_0$ cm per dyne, where A_d is the effective piston area of the cone in square centimeters and V_0 is the net volume of the box in cubic centimeters. The

Fig. 37. Impedance of circuit of Fig. 36.

"compliance" is the reciprocal of this value. This stiffness raises the natural frequency of the speaker. If the enclosure includes absorbing material, this stiffness will be altered by the reactance seen at the surface of the material. Each square centimeter will dissipate $P^2 \times 10^{-7}/r_B$ watt, where P is the sound pressure in the box and r_B is the resistance per unit area for sound of normal incidence on the absorb-

ing material. From this the equivalent resistance in parallel with the box stiffness may be obtained.

The l-f equivalent electrical current of such an enclosure is shown in Fig. 29. Here Z_D is the electrical equivalent of the diaphragm alone; S_d, r_d, and m_d are the stiffness, resistance, and mass of the diaphragm measured *in vacuo*. The electrical equivalent of the air load including radiation impedance is Z_A; S_a is the effective enclosure stiffness, r_a the total air or fluid resistance (enclosure and grill cloth or opening resistance if any, and radiation resistance), and m_a is the effective air (radiation-plus-enclosure) mass. Normally the parallel value of Z_D and Z_A or a single parallel "antiresonant" circuit is shown but the contributions of individual elements are then not as clear. Since the electrical circuit elements are *inverses* with respect to M^2 [see Eq. (9)], the stiffness appears as an inductance and the mass as a capacitance.
Fig. 38. Total distortion of open-back cabinet and of the same cabinet enclosed as shown in Fig. 35; same speaker and electrical input in both cases. Low-frequency distortion is much reduced because diaphragm sees high antiresonant impedance of enclosure and therefore has only small displacement whereas air in port (which lacks the nonlinear edge stiffness and nonuniform flux of the speaker) moves with large displacement.

If the volume is small enough or the natural frequency of the speaker out of the enclosure low enough, the enclosure and not the diaphragm stiffness will control the natural frequency.

There is little to gain in making the mechanical stiffness of the speaker less than one-fifth that of the enclosure S_a given above, since this mechanical stiffness raises the resonant frequency by only 10 per cent and it permits using a good mechanical suspension and good centering, thereby economizing on magnet structure volume and cost. Figure 39 shows what the resonant frequency of an 8-, 12-, and special 15-in. speaker (designating sizes) would be as a function of *net* enclosure volume (gross volume less volume of speaker cone and magnet structure) if the speakers had *no* mechanical stiffness. A typical 1-in. voice-coil 8-in., a typical 1.5-in. voice-coil 12-in., and a special 15-in. "woofer" were assumed. The 15-in. has an 80-g l-f dynamic mass, including radiation or air mass, because of the heavy voice coil and cone used to optimize its performance as an l-f speaker. The 12-in. speaker has a dynamic mass of only 27 g but because of its reduced diaphragm area sees only one-third as much acoustical or air stiffness in the same enclosure, hence resonates at the same frequency as the 15-in. speaker. The 8-in. diaphragm assembly has a mass of only 6.8 g but resonates at a lower frequency because of the lower acoustic stiffness it sees.

From Fig. 39 note that an enclosure of say 1.5 cu ft would result in a resonant frequency of 96 cps for either the standard 12-in. or special 15-in. speaker even if they had no mechanical stiffness. If the enclosure volume is kept at 1.5 cu ft the cost in dollars and/or efficiency of lowering the resonant frequency is high. If we halve the frequency to 48 cps by keeping the same voice coil and magnet but increase the dynamic mass by a factor of 4, by using a heavier cone or otherwise, the efficiency in the useful band drops 12 db, or to one-sixteenth its original value above 96 cps. The efficiencies of the modified and unmodified speakers converge at 46 cps. The original efficiency cannot be maintained in practice with the lower resonance because the energy in the air gap cannot be raised by the required factor of 16 (when all the mass increase is in voice-coil conductor) without prohibitive cost and magnet size increases.

The compromises between enclosure size, radiated power, and resonant frequency can be kept in mind by reviewing the following factors. The stiffness seen by the diaphragm is proportional to the square of the diaphragm area. The efficiency in the pass band drops 12 db for each octave the resonant frequency is lowered, corresponding to 6 db for a 29 per cent and 2 db for a 10 per cent lowering of the resonant frequency. If the diaphragm is driven at constant amplitude, the radiated power varies with the square of the diaphragm area.
FIG. 39. Resonant frequency of standard 8-in., 12-in., and a special 15-in. speaker as a function of net enclosure volume for the idealized case of no diaphragm mechanical support stiffness.

In practice, therefore, the resonant frequency should not be lowered needlessly. With good music listening in mind 60 to 70 cps is adequate. Lower frequencies are of primary interest to the experimenter and "acoustic effects" man. If the enclosure must be small, the diaphragm may be small to lower the resonance but the radiator power should be correspondingly reduced. The most satisfactory way of keeping reasonable efficiency and l-f response is to use an adequate enclosure volume. A minimum of several cubic feet is desirable. If greater l-f output is needed, a properly designed vented enclosure should be considered.

A total enclosure is sometimes called an *infinite* baffle. While it resembles one in preventing front and back wave interference, it has two important differences which make this designating term undesirable. The enclosure adds an air impedance to the rear of the diaphragm, which may be very different from that seen in an infinite baffle. An infinite baffle restricts the radiation to a hemisphere, and the radiation impedance seen by the diaphragm is given by Fig. 11. If the enclosure is used outdoors, the radiation resistance which the outside of the diaphragm sees at low fre-

quencies is only half this value and the reactive part approximately seven-tenths this value. In practice the useful efficiency is almost halved at low frequencies. Indoors the impedance seen will depend on the environment as described in Sec. 5, also in Room Acoustics, below.

27. Vented Enclosures. The idea of putting a vent or "port" in an enclosure is very old. It was first done to provide "pressure relief." In more recent types, known as "vented" enclosures, detailed consideration has been given to the very important effect of the mutual impedance between the port and diaphragm. The port area is large and the port is near the diaphragm to increase the mutual radiation resistance and extend the frequency range over which it is effective (see Sec. 7). Such an enclosure is shown in Fig. 35. The effective or virtual diaphragm in the opening is coupled internally through the stiffness of the air in the enclosure to the diaphragm. It is also coupled externally. The equivalent l-f circuit is shown in Fig. 36. Impedance Z_D corresponds to Fig. 29 and r_a and m_a correspond except that the mutual-radiation impedance must be added.
FIG. 40. Total sound power radiated by cabinet for which distortion is shown in Fig. 38. Shape of low-frequency response may be varied between wide limits depending on enclosure volume, port area, and speaker used.

The vent and enclosure have therefore added one *LRC* circuit. The effect of this is to shift the back-side-cone radiation by nearly 180 deg above the frequency at which the port mass m_p and box stiffness *viewed from the port* are resonant when the cone is blocked. For about one-third of an octave above and below this frequency most energy is radiated by the port. Although the diaphragm and port radiation are out of phase below this frequency, the port radiation greatly exceeds the diaphragm radiation near this frequency.

The enclosure is made as compact as possible. The port can be placed near the diaphragm to increase the mutual-radiation resistance since the phase shift is not primarily due to transmission time delay but occurs because the acoustic circuit goes through antiresonance, the phase shift occurring suddenly at this frequency. In properly designed enclosures, advantage is taken of a large mutual-radiation resistance to improve the l-f efficiency. Very little absorption in the enclosure is wanted at low frequencies to take maximum advantage of backside radiation. At frequencies of several hundred cycles or more where the port radiates negligible sound the enclosure is made absorbent to avoid "box" resonance. The advantages of vented enclosures are: (1) backside radiation is used to increase substantially the l-f output; (2) most of this output comes from the port which has no nonlinear diaphragm suspension stiffness to produce nonlinear distortion; (3) antiresonance of the enclosure occurs near the lower frequency of maximum radiation so the diaphragm amplitude is much less than it would be otherwise. The result of these factors on nonlinear distortion reduction is shown in Fig. 38, in which the effect of converting an open-back cabinet to a vented port enclosure of the same internal volume is shown. The change in response is shown in Fig. 40.

While a large number of vented enclosures, which differ in physical appearance, have been made they all have substantially the equivalent circuit shown in Fig. 36. The inclusion of absorbing material may introduce a resistance in the box stiffness branch, and various values of the parameters are used to modify the response. In

some instances, the relative increase in l-f response is actually obtained by reducing the middle-frequency response.

28. Transmission-line Speaker. The phase and amplitude of the backside radiation of a cone may be altered by coupling a conduit or acoustic transmission line to it. In early types the multiple-resonant properties of such a line were used to influence the response. In a more recent type, known as the labyrinth, the line is folded to conserve space and made highly dissipative (see Fig. 41). Phase shift between the diaphragm and port or open end is due to time of transmission in the line. At very low frequencies the line is a small fraction of a wavelength long, the phase shift is negligible, and the port and diaphragm radiation are out of phase. When the line is $\lambda/4$ long, it acts as an impedance inverter (as in the electrical case); the cone sees a high impedance, and the radiation from the port is a maximum. Nonlinear distortion is therefore reduced at and near this frequency. The resonant frequency of the diaphragm may be placed at this frequency to aid damping. Between this frequency and the one for which the line is $\lambda/2$ long, the port phase shifts gradually but maintains some component of its radiation in phase with the diaphragm (neglecting separation between the port and diaphragm) outside the line. Because of the infinite series of resonant and antiresonant frequencies of the line, high absorption must be introduced to prevent the production of objectionable resonances and radiated out-of-phase components of the port. Most of the rear-side radiation is therefore absorbed. The comparison of the responses of an open-back cabinet and labyrinth is shown in Fig. 42.

FIG. 41. Labyrinth type of transmission-line speaker. Phase shift of backside radiation is obtained by time of transmission delay in line.
FIG. 42. Relative response of open-back cabinet A and labyrinth B.

ROOM ACOUSTICS

29. Room Characteristics. The trend in the theory of room acoustics is toward considering the source of sound, the room, and the sound receiver or "sink" all as part of a unified dynamical system. This is required to bring out the interaction between source, sink, and room and their effects on the steady-state and transient aspects of sound transmission in the room.

In this theory the room is considered as an assemblage of resonators and the walls of the room as terminal impedances determining absorption and reflection. A rectangular room has a triple infinity of resonant frequencies. If the wall impedances are high pure resistances, these frequencies are given by

$$f = 17{,}140\left[\left(\frac{n_x}{l_x}\right)^2 + \left(\frac{n_y}{l_y}\right)^2 + \left(\frac{n_z}{l_z}\right)^2\right]^{1/2} \tag{15}$$

where $n_x, n_y, n_z = 0, 1, 2, \ldots$

l_x, l_y, l_z = dimensions of rectangular room, cm

The distribution of these "allowed" frequencies (at which resonance occurs) may be graphically shown as in Fig. 43 by a three-dimensional plot in "frequency space." Each vector to a lattice point is associated with a "natural frequency" or "normal mode" of the room. The shortest vector, corresponding to the lowest frequency, is determined by the longest dimension of the room. The direction of the vector from the origin to a lattice point indicates the direction of excitation of that frequency in the room, and the length of the vector is proportional to its frequency.

At low frequencies there may be an appreciable frequency interval between the natural frequencies if the room is small. At high frequencies the number of natural frequencies in a given frequency interval is proportional to the square of the frequency.

FIG. 43. Distribution of resonant frequencies for a rectangular room with side lengths l_x, l_y, and l_z. The length of a vector from the origin to each lattice point indicates the frequency and the direction of the vector indicates the direction of the corresponding standing wave. The velocity of the sound wave c is given by Eq. (1).

30. Reverberation. Using this concept of multiple natural frequencies, the decay of sound in a room may be described as follows: Assume energy has been supplied to the room until the energy level is constant; *i.e.*, the rate of absorption at the boundaries equals the rate of supply to the room. The resulting standing-wave system depends not only on the room and frequency but on the location and orientation of the source. When the source of energy is stopped each individual mode of vibration of the room will decay exponentially at its own frequency and the combined effect of these is called *reverberation*. Only the modes having allowed frequencies near the fre- contain appreciable energy. quency of the steady-state excitation will

By definition the reverberation time is the time required for the mean energy density in the room to drop 60 db. While this mean may be the result of a large number of rates of decay each of which is individually exponential, the combined value in general is not given by a single exponential term. This accounts for the fact that the slope of the mean-energy-density time-decay curves for the average room are not uniform and therefore for the fact that the apparent reverberation time depends on the time interval over which the decay is averaged. If the absorption is moderate the approximate reverberation time in seconds is given by

$$T = \frac{0.00161V}{-A \ln (1 - \alpha)} \tag{16}$$

where V = room volume, cc

$\alpha = (A_1\alpha_1 + A_2\alpha_2 + \cdots)/A$ total room absorption

A_1, A_2, etc. = areas, sq cm, having absorption coefficients α_1, α_2, etc., respectively

A = total boundary area of room

Corresponding to this type of energy decay in the room, there is a growth curve. When a source suddenly emits energy, each of the excited modes absorbs energy in an exponential manner. This occurs until the asymptotic or steady-state value is reached after an infinite length of time. When this is reached, the acoustic power supplied to the room must equal that absorbed at the room boundaries. By definition the absorption coefficient α of the boundary is the fraction of the incident energy absorbed for a specified angle of incidence. The intensity I of a sound wave [Eq. (2)] is a measure of the energy per square centimeter per second. The total intensity is made

up of two parts: that due to the reverberant sound and that due to sound received directly from the source. The acoustic power radiated by the source is related to the total intensity by

$$P_a = \frac{I}{\frac{1-\alpha}{A\alpha} + \frac{1}{4\pi r^2}} \quad \text{watts} \tag{17}$$

where P_a = radiated power, watts
I = total intensity, watts per sq cm
r = distance between source and point at which I is measured, cm

Chairs, metal or wood	150	170	200
Chairs, theater, heavily upholstered		2,500-3,000	

With the usual placement of listeners in studios and theaters the contribution of the second term is small in the audience space, and most of the intensity is due to the reverberant sound. The foregoing assumes that I is uniform throughout the room. This is reasonably valid if the room has a reverberation time near optimum, if the sound source is not highly directional, if the room is many wavelengths long, if its proportions are neither too cubical nor too elongated, and if large flat surfaces are broken up by diffusing shapes or patches of absorbing material.

When the direct sound intensity is relatively small, Eqs. (16) and (17) may be combined to yield

$$I = \frac{P_a e^{-0.00161V/TA}}{A(1 - e^{-0.00161V/TA})} \quad \text{watts/sq cm} \qquad (18)$$

This relation may be used to obtain the efficiency of a loud-speaker by measuring the intensity produced, calculating the acoustic output from Eq. (18), and comparing that with the electrical power available to the speaker from the electrical source.
FIG. 44. Dependence of optimum reverberation time on room volume for various applications. Various authorities differ by 20 per cent or more from the indicated values so this deviation may be considered permissible.

In Table 3 are listed the absorption coefficients for some representative proprietary acoustical materials and objects, and the total absorption for persons and seats, for use in Eq. (12).

31. Room Power Requirements. If we know the desired sound intensity, the acoustic input power P_a required to produce it may be obtained either from Eq. (17) by knowing the total room absorption or from Eq. (18) by knowing the room volume and reverberation time. If the shape of the room is unknown, the surface area A may be approximated by $SV^{2/3}$, where S is a factor between 6 for a cubic room and about 12 for an elongated room. Desirable reverberation times in terms of room volume for various uses are shown in Fig. 44. The values for speech only will lie near or below the lowest curve and are seldom realized except in acoustically treated rooms. Typical schoolrooms with average attendance, for example, usually have reverberation times well up toward the upper music range.

Speech articulation increases rapidly with intensity up to an intensity level of 40 db or 10^{-12} watt per sq cm and more slowly to 50 db or 10^{-11} watt per sq cm. If room noises are present, the speech intensity should exceed these by at least 10 db and preferably by 20 db or more. In conversational speech the person speaking

radiates about 10^{-5} watt. Loud speaking requires 10^{-3} watt. If a loud-speaker is to simulate a person speaking loudly, its acoustic output should be at least 10^{-3} watt, which, for a 1 per cent efficient loud-speaker radiating all its output into the room, means an electrical input of $\frac{1}{10}$ watt.

There is considerable difference of opinion on what constitutes acceptable levels of reproduced sound. Values of electrical power input which have been suggested for theater use are shown in Fig. 45. These are based on the use of speaker systems with average system efficiencies of 25 per cent. The trend is toward larger inputs to get enhanced dramatic value in the reproduction.

In Fig. 46 are shown the *minimum* recommended acoustical power inputs to rooms having acoustical characteristics suitable for sound motion-picture theaters, for a sound pressure level of 80 db. This is satisfactory for speech in a fairly quiet room.
FIG. 45. Recommended amplifier output for motion-picture reproduction. Speaker system efficiency assumed to be 25 per cent; so acoustic input to theater is one-quarter indicated electrical input. Trend is toward higher values.
FIG. 46. Acoustical power to produce 80-db level in rooms acoustically similar to sound motion-picture theaters.

For music reproduction, various authorities recommend inputs some 15 to 25 db higher to simulate the actual orchestra. This increases the amplifier power needed some 30 to 300 times above the recommended minimum for speech. From this it may be seen that differences of opinion may account for large performance and cost differences.

32. Acoustic System Characteristics. When a sound receiver is included in the room with a source, we must consider the reaction of the room on it. The most common receiver is a listener. Because of the difficulty, however, of making objective measurements of what is going on in the listener's central nervous system, it is more convenient, although only approximately correct, to substitute one or more microphones for the listener.

For sake of simplicity, assume we have a loud-speaker as a source and a microphone as a receiver or sink, each with two accessible terminals. Since no source of energy is assumed in the room, these four leads may be considered the terminals of a passive quadripole or four-terminal network. From circuit theory we know that the measurement of three independent quantities will completely specify the performance of this quadripole at any one frequency. By analogy with the purely electrical case we may define the ratio (complex) of the current through a specified microphone load to the input voltage of the speaker as a transfer admittance.

A curve giving the magnitude of this quantity for a speaker and a microphone

mounted in diagonally opposite corners of a rectangular 18- by 20- by 11-ft room is shown in Fig. 47. This transfer admittance is what might be called the response curve of the loud-speaker measured in this room with designated locations for the source and microphone and with the particular microphone employed. As would be expected from the complicated equivalent circuit of the room, this transfer admittance varies by a large factor with frequency and exhibits a large number of maximums and minimums at high frequencies. In passing it may be noted that the impedance of the boundary of this room varied appreciably with frequency and therefore the locations of the resonant and antiresonant frequencies of the "electroacoustoelectrical network" do not occur at the frequencies predicted by constant boundary impedances.

Considering the matter in this light, we see that this response curve depends on the type of speaker, microphone, their location in the room, the geometry of
Fig. 47. Transfer admittance or "response curve" of a speaker, room, and microphone or electroacoustoelectrical transducer. Speaker and microphone are in diagonally opposite corners of an 18- by 20- by 11-ft room.

the room, and the impedance of the room boundaries and therefore the impedance of the entire dynamical system seen from the acoustic terminals of the speaker and microphone.

The loud-speaker supplies maximum energy to the room when the impedance seen by the diaphragm looking into the room is the conjugate of the impedance looking back into the diaphragm with the speaker connected to its generator or amplifier. Since the latter impedance is usually high, the speaker supplies maximum power when the room impedance is high, which occurs (by definition) when the ratio of the pressure to particle velocity is high, *i.e.*, when the speaker is near a pressure maximum. A pressure-actuated microphone gives maximum response at a pressure maximum. The maximum peaks in the transfer admittance of Fig. 47 therefore occur when both the microphone and speaker are near pressure maxima. No resonance pressure maximum occurs at the speaker below the lowest resonant frequency of the room, and good l-f response is therefore hard to obtain in small rooms.

The apparent damping or Q of a mode of the system may be obtained by steady-state sharpness of resonance methods corresponding to those employed in circuit investigations. With negligible dissipation due to losses in the source, air, and sink, the damping of a particular mode is an indication of the absorption of energy at the boundary. From this damping coefficient the effective absorption coefficient of the boundary under the conditions determined by the mode may also be obtained. The simplest result is obtained when the wave front is parallel to the walls on which it is

incident. The same apparent absorption is obtained from the transient decay of the same mode.

Likewise, by analogy with the electrical case, we may think of the transient current which flows through the microphone load when a unit d-c potential is suddenly supplied to the speaker terminals as the "transfer indicial admittance" of this electroacousto-electrical network. Viewed in this light the transient response of the speaker itself (a small part of the dynamical system) or the transfer indicial admittance of the loud-speaker and microphone mounted in a free field where no reflections are present takes on much less significance.

We know experimentally that any room which is considered a good acoustical listening environment has appreciable reverberation and therefore that the rate of decay of the energy in the resonators of the room is only moderate. Experimentally it has been found that the rate of decay of the modes of the speaker itself measured in a free field is of the same order. If the loud-speaker is loosely coupled to the room, *i.e.*, if the room impedance seen by its diaphragm is small as compared with the impedance seen looking into the diaphragm, then we may loosely think of the loud-speaker as converting the unit d-c emf into a number of damped sinusoidal terms (one corresponding to each mode of the speaker), which in turn excite the room. The spectral composition of a single damped sinusoid for two rates of decay is shown in Fig. 7. From these we see that, if the rate of decay is large, the number of room modes excited may be large, because of the broad frequency spread of the energy exciting the room. Actually, of course, we should only think of the dynamical system as a whole and the above explanation as a simplification of the problem.

Experimental curves of this transfer indicial admittance are what one would predict from the theory. If the speaker is loosely coupled to the room, if its damping when it looks into a small acoustical impedance is low, and if an undamped resonant frequency of the speaker lies near one of the resonant modes of the room, the transient term looks like a typical one for two coupled circuits. That is, there are two prominent rates of decay containing the combined effect of the two important resonant frequencies (the speaker and room). On the other hand, if the speaker is highly damped when looking into a high acoustical impedance, if the driving point impedance of the room at an undamped natural frequency of the diaphragm is high, and if the room is large or its dimensions are so chosen that there are a number of resonant frequencies near an undamped resonant frequency of the speaker diaphragm, then the transient term consists of the superposition of a large number of damped sinusoids. In this case it may be seen that elimination of the term due to the loud-speaker would cause a negligibly small change in the apparent transient response of the system. This was verified in an unreported investigation in which it was shown experimentally that, if the fundamental speaker mode was eliminated by the use of a properly chosen electrical network, the aural result in reproduced speech and music was small unless the damping of the speaker radiating into a free field was unusually small.

The more important practical implications of the above (see also Sec. 7, Mutual Radiation Impedance) are the following: (1) The loud-speaker should preferably be mounted in the corner of the room. In this position the greatest number of room resonances are "excited" and the most energy is supplied to the room. (2) The *average* l-f radiation is a maximum when the speaker is as near the floor (or ceiling) as possible and in the room corner. Next most desirable location is near floor (or ceiling) and side wall. (3) At any one frequency, maximum radiation is obtained when the room impedance seen by the diaphragm is the conjugate of the impedance seen looking back into the diaphragm, that is, for the location which makes the *combined* speaker and room resonate. Such a maximum may not be obtained if the longest room dimension is less than roughly a half wavelength long. (4) Because of this and the small number of resonant frequencies which occur in small rooms at low frequencies, small rooms do not normally permit the best l-f reproduction. (5) Corner positions also permit improved h-f response because of the smaller solid angle the radiation has to cover. (6) The l-f transient response of the speaker itself is

not so important as is generally supposed because the *desired* transient response of the room, which is a necessary property of a listening room judged to be good by trained listeners, helps obscure this "distortion."

OBJECTIVE LOUD-SPEAKER TESTS

The following more important characteristics of a loud-speaker must be determined in any complete test: response-frequency, efficiency-frequency, directional, impedance, and distortion.

33. Response-frequency Characteristic (Steady State). A response-frequency curve of a speaker is a curve graphically depicting the sound pressure produced at a designated position in the medium, the electrical input and acoustic environment being specified. Frequency discrimination is the most important form of distortion in many loud-speakers, and the response curve attempts to indicate quantitatively the amount present. Since the ear is primarily responsive to the sound pressure, the ordinate of the curve is made proportional to it or to its average value in a specified region.

The response curve is obtained by connecting the loud-speaker to a variable frequency source of specified internal impedance and constant specified internal voltage. The pressure at one or more points in the medium is measured as the frequency is varied slowly enough so the resulting measurement does not differ appreciably from the steady-state value.

A "free-field" response curve is made outdoors or in an anechoic ("dead") room in the absence of unintended reflecting surfaces and is probably the most useful single curve showing the loud-speaker performance for outdoor applications. Curves of this type are valuable because (1) the direct incident sound from the source in various directions may be accurately determined and a close estimate made of the direct sound indoors; (2) the acoustic environment is relatively simple since only intended reflecting surfaces are included. The efficiency of the unit may then be accurately obtained from this environment at some frequencies and estimated at others, since the impedance seen by the diaphragm will change slowly with frequency, *i.e.*, the transfer admittance of the speaker, air, and microphone is a smooth curve. (3) The specified test conditions may be duplicated relatively easily at various laboratories, permitting significant comparison of test results. The construction of identical normal listening or live test rooms, however desirable, would be difficult, partly because of differences of opinion on an "average" room and partly for economic reasons.

By "intended" reflecting surfaces is meant those that are an intended part of the radiating system. Frequently a cabinet or enclosure is measured outdoors in the absence of all reflecting surfaces, *i.e.*, radiating into a solid angle of 4π steradians or a complete sphere. This is usually undesirable since most enclosures are intended to operate on a floor and against a wall, which adds two intended reflecting surfaces and primary images (see Radiation Impedance). If the enclosure is intended to operate in a room corner, there are three important primary images. The impedance seen looking into these reduced solid angles of π and $\pi/2$ steradians, respectively, is very different from the 4π case and usually results in an error of the order of 6 to 8 db at low frequencies. The error is especially large in the case of compound sources such as vented enclosures. The measured nonlinear distortion usually differs by a much larger factor.

Outdoor measurements into solid angles of π (wall and floor) and $\pi/2$ steradians (corner) are made by constructing large rigid nonabsorbing surfaces.

Other intended parts of the speaker such as the baffle, horn, and enclosure should, of course, be specified. The normal impedance or the impedance looking into the signal terminals of the speaker with the acoustical load (acoustical environment), used when the response curve was obtained, should be plotted. Both the angle and modulus of this impedance are required if the response of the speaker with any source impedance other than that employed in the test is to be calculated.

If a space average of the pressure is obtained by moving the microphone or by using multiple microphones, details of the method should be given. If a warble tone or noise generator is used to get a "moving frequency average" of the transfer admittance, the spectral composition of the source should be specified. These expedients and the one involving motion of the loud-speaker, which is usually unsatisfactory, are recommended only for indoor measurements when the room does not provide approximately free-field conditions.

Normal listening-room measurements are made with the loud-speaker mounted in its intended position in a typical listening room. As noted under Room Acoustics, the room impedance seen by the loud-speaker depends on the characteristics and location of the source itself (diaphragm sizes, locations, and modes of vibration), the
FIG. 48. Response of one speaker as measured by three different companies, showing the futility of relying on response curves without a complete knowledge of the specific test, acoustic environment, and method.

geometry of the room, and the impedance of its boundaries. This means that the energy supplied the room depends on the particular room and speaker location chosen. This is frequently used as an argument against this type of test. Since the results obtained in reasonably similar rooms, with similar speaker locations in each, differ by only a moderate amount, this disadvantage does not outweigh the many important advantages of this type of test, some of which are: (1) the impedance seen by the loud-speaker (including cabinet or enclosure), averaged over a small frequency interval, is closer to the average impedance seen under operating conditions than the impedance seen under the usual (4π steradians) outdoor test conditions; (2) calculation of the indoor from the outdoor performance is only of academic interest when hundreds of response curves are to be obtained, because of the labor involved; (3) ready comparison of the results of objective and subjective or listening tests in the same room is possible if the room is a good listening room; (4) one is not at the mercy of the weather; and, most important, (5) test facilities are readily provided in almost any organization.

Three large laboratories measured one speaker and plotted what they would publish as the response-frequency graph of the speaker. The results are shown in Fig. 48. This does not indicate any error in measurement. Actually different things were measured in each case. The curves indicate that response curves must be interpreted with great care and then only by a person familiar with the many factors involved. No experienced speaker designer or user thinks of choosing a speaker solely or even largely on the basis of a response curve.

34. Efficiency-frequency Characteristic. If the free-field-pressure response at a sufficient number of points on a spherical surface centered on the diaphragm is obtained, the total acoustical output may be calculated.

The efficiency-frequency curve of a speaker corresponds to the response-frequency curve except that the ordinate indicates the efficiency (usually "rated" or system). In a typical listening environment and listener location the direct incident sound energy, which would be approximately indicated by the free-field response-frequency curve at the listener's location with respect to the speaker, is only a small fraction of the reflected sound energy. A curve which gives the pressure, averaged over the useful listening region, then indicates the probable pressure the listener will experience. If absorption at the room boundary is independent of frequency this will be proportional to the total energy emitted by the speaker. Efficiency-frequency or space-averaged response-frequency curves are therefore very useful in interpreting indoor operation. Outdoor response-frequency curves at various angles off the speaker
FIG. 49. Variation in total sound power radiated by a bass reflex enclosure into a room as source impedance (impedance match) is varied. Generator or source voltage constant for each curve but arbitrarily raised as the source resistance was raised to maintain constant acoustic output at 400 cycles.

axis, with the speaker radiating into approximately the solid angle it will see indoors, are also important since the listener weights the direct incident sound energy more heavily than the same energy if in a reflected wave. Haas[1] has shown that this arises from the fact that the initial wave takes control of the listening mechanism in such a way that a subsequent identical wave delayed by from 5 to 30 msec has to exceed the first by the order of 10 db, even if coming from a different direction, to be reliably identified as a separate disturbing signal. This also accounts for the fact that it is very desirable to so mount reinforcing speakers in speech systems that their air path distance to listeners is from 6 to 35 ft greater than the distance from the microphone to the listeners. The success of the directional speaker located some distance directly over or even a little behind the microphone in a voice-reinforcing system is accounted for primarily by this factor.

SUBJECTIVE LOUD-SPEAKER TESTS

35. Listening or Subjective Tests. Listening tests are a necessary part of the complete test of a loud-speaker. While physical measurements are valuable in design work and in quantitatively determining some performance criteria, they cannot at present completely specify the subjective performance. Because of the apparent simplicity of listening tests many important factors are frequently neglected, with the result that many tests are meaningless and others actually misleading.

In both indoor and outdoor tests all precautions should be taken that are used in

[1] Haas, v. H., Über den Einfluss eines Einfachechos auf die Hörsamkeit von Sprache, *Acustica*, **1** (2), 49, 1951.

physical or objective tests. The only essential difference is that the listener is substituted for the microphone. The properties of the ear and listener must therefore be considered in interpreting the results.

36. Relative-loudness Efficiency. The most common test is one to determine the relative-loudness efficiency of two speakers. An attenuator in the amplifier which does not alter its response is adjusted (usually with a relay which also switches the speakers) to attenuate the input to the louder speaker by the amount required to make the speakers equally loud. The required attenuation of the louder in decibels is their relative loudness efficiency in decibels. The relative loudness will depend primarily on the spectral composition of the test signal, the response-frequency characteristic of the speakers, and on the sound intensity. Tests on the speaking and singing voice and various types of music are usually averaged. A valuable signal source for this and response-frequency tests is a "flat" noise source, or one in which the energy is uniformly distributed with frequency. This particular spectral composition ensures energy at all frequencies at which significant differences in the speaker response may occur.

FIG. 50. Response of moving-coil speaker with 8-ohm voice coil to an electrical pulse as source resistance is varied. Minor irregularities in curves are due to high-frequency modes of vibration of diaphragm.

37. Response-frequency Characteristic. Apparent subjective response-frequency tests may be made with the same signal source used in the loudness tests. Since the listener is not mobile, "space-averaging" methods employed with microphones cannot be used and "frequency-averaging" methods are employed. While noise sources are occasionally used in objective tests, they have unfortunately been neglected in subjective tests, where they are of special value because the trained ear can quickly appraise response differences which are missed if the signal source contains no energy at the frequencies at which differences occur.

38. Distortion Characteristic. Except with a single- or double-frequency input (the latter to determine intermodulation) it is difficult to determine the distortion characteristic of the speaker itself. With one or two simultaneously applied frequencies the input to the speaker is readily determined when the normal impedance of the speaker is known. This is not true of a signal of random energy distribution, and therefore with such a signal the apparent input to the speaker is not readily determined unless the normal impedance is relatively independent of frequency. When the *speaker* distortion characteristic is desired, the amplifier should be capable of supplying many times the rated input power to the speaker without distortion because of the high ratio of peak to average energy in speech and music (see these sections). Much overload charged to speakers is amplifier overload.

What is usually measured is the *system* distortion characteristic. Since amplifier overload almost invariably occurs at about the level at which speaker overload occurs in an economically planned system, what is evaluated is the combined system overload. In this case the speaker with the most restricted h-f response (other factors
being equal) will have the best *system* overload rating since annoying h-f distortion products are attenuated.

There is no standard for speaker input power rating, but in practice a speaker rated at X watts will "handle" the output of an X-watt amplifier, which is not overloaded, with speech or music (complex wave) input (see Motors and Secs. 1 and 18). The rating does not indicate the power the speaker will handle at a single frequency but takes advantage of the *normal* (no heavy bass or treble accentuation) spectral composition of speech and music. To avoid the trouble in determining the signal level across the speaker, with its variation in normal impedance, the grid voltage on the output stage may be measured. The signal input is raised until perceptible distortion results. The peak grid voltage is then measured with an indicator having a negligible time constant, such as a cathode-ray tube. A resistance equal in value to the magnitude of the nominal loud-speaker impedance is substituted for the speaker. The power dissipated in the resistance load with a 400-cps signal having the same maximum value as the maximum signal is considered (since it includes the output stage) the speaker input power rating.
Table 4. EIA Standard Mounting Dimensions for Direct-radiator Speakers

Nominal speaker size, in.	Hole arrangement	Mounting diam, in.	Min hole diam, in.	Baffle* hole diam, in.
3½	*b*	3$^{15}/_{16}$	$^{3}/_{16}$	3⅛
4	*b*	4$^{11}/_{16}$	⅛	3¾
5	*a*	4$^{11}/_{16}$	⅛	4⅛
5¾	*a*	5⅜	⅛	4¾
6½	*a*	6⅛	⅛	5⅜
8	*a*	7⅝	$^{7}/_{32}$	6¾
10	*b*	9⅝	$^{7}/_{32}$	8¾
12	*b*	11$^{9}/_{16}$	¼	10¾
15	*a*	14$^{9}/_{16}$	$^{17}/_{64}$	13¼

* Not an adopted standard.

Intermodulation tests performed by measuring the distortion products generated when two sinusoidal signals of different frequency are applied are of value in design work but of limited value to the user because the results may be confusing or even misleading. If a high-amplitude fixed low-frequency signal (usually between 60 and 400 cps) is applied and a second signal, normally of constant but reduced voltage and variable from 1 to 20 kc, is also applied, through a low-distortion mixer, the intermodulation products can be measured. The converse may also be done; namely, apply a fixed h-f and vary the l-f signal. In a typical speaker these distortion products will be found to vary markedly with the frequency of the applied signals. Because of the marked frequency dependence preselected frequencies of the type

used in amplifier measurements may be very misleading. No single figure of merit based on the physical measurements has been found which correlates at all satisfactorily with the objectionability of the distortion products assessed by a listening jury.

39. Outdoor Tests. These should be conducted so the listener subtends the same or a known angle with each source. The sources should be mounted so their mutual-radiation impedance does not influence the result. Separating the sources by several times the diameter of the cone or horn mouth usually suffices. The energy absorbed by the unused speaker will be more nearly independent of frequency if the voice coil of the unused speaker is short-circuited. Unwanted reflecting surfaces should be avoided.

40. Indoor Tests. The speakers should be separated by several times the diameter of the cone or horn mouth to minimize mutual-radiation impedance. This is particularly true if the speakers are mounted on a common open baffle. Some coupling between the sources will always exist because of the transfer admittance between the two in the room (see Room Acoustics). It is important to mount the speakers symmetrically with respect to the room and listener in order to provide similar coupling between each source, the room, and the listener.

CHAPTER 12

NONLINEAR CIRCUITS

By Keats A. Pullen[1]

1. Definition. A linear circuit has a transfer function (ratio of output to input) which is not a function of any characteristics of the input signal (amplitude, frequency, or phase, for example); it does not introduce any variations or alterations of the shape of the wave. It may introduce a time delay, that is, it may repeat the wave exactly but with a small delay. Conversely, a nonlinear circuit has a transfer function which is dependent on one or more characteristics of the input signal. Whereas the linear circuit introduces a constant (or zero) time delay and no change in the wave form, the nonlinear circuit may introduce a variable delay and a change of wave form.

2. Types of Nonlinear Circuits. The types of nonlinearities which can be obtained with conventional circuits may be divided into four principal groups:

1. Frequency
2. Phase
3. Amplitude
4. Time-induced amplitude, or LTV (linear time variant, Sec. 89)

In actual practice, it is often difficult to classify some nonlinear conditions exactly because two or more types of conditions may occur simultaneously. For that reason, the discussion considers separately each particular type of nonlinearity in relation to its prime applications. For example, most devices which generate frequency distortion also produce phase distortion. In a similar manner, a device capable of generating amplitude distortion may also produce an amplification which varies with time, thereby introducing a time-controlled type of amplitude nonlinearity.

3. Frequency Nonlinearities. Circuits having nonlinear frequency characteristics show an amplification which varies as a function of frequency. In many of the more routine applications of electronics, for example, amplifiers and related devices, a circuit is intentionally adjusted to have a minimum variation of amplification with frequency over a specified range (the amplification may be less than unity and represent a loss). There are also many applications in which the variation of amplification with frequency is used to accomplish specific results; it is the purpose of this and the following sections to show typical applications and briefly note the techniques used in designing circuits to provide a variable amplification as a function of frequency.

The simplest circuits having a frequency type of nonlinearity normally show a constant amplification over one range of frequency and an amplification which changes by a ratio of 2:1 for each octave change of frequency in another range (change of frequency to either half or twice the initial value).

Devices which possess one type of characteristic in one range of operation and another type of characteristic in another range have a transition region in which neither characteristic alone applies. In this region the characteristic is a combination of the two. The *critical frequency* or *transition frequency* is that frequency at which the impedances of the two elements are equal, or $|Y_1Z_2| = 1$. It separates the two ranges and specifies the intersection point of the tangents to the two sections of a plot, on a loglog scale (Fig. 1) of the amplification as a function of frequency. The transition region extends from just under half to just over twice the critical frequency.

[1] Aberdeen Proving Grounds.

4. Integrator Circuits. Circuits which offer no hindrance to the passage of signals having frequencies well below the critical frequency but which attenuate the amplitude to half for each doubling of the frequency above the critical frequency may be called integrating circuits. In their simplest form, there are four basic combinations
FIG. 1. Basic L-section network.

of R, C, L, or constant-voltage or -current sources, used in pairs, which may be used to form integrator circuits. They are:

1. RC integrators (passive)
2. LR integrators (passive)
3. Capacitive constant-current integrators (active)
4. Inductive constant-voltage integrators (active)

Each of these is discussed in turn after an examination of the basic operating conditions for the series-shunt, or L-section, circuit.

5. Series-shunt, or L-section, Circuit. The function of this type of circuit may be determined, as indicated in Fig. 1, in terms of the equation

$$K = 1/(1 + Y_1Z_2) \tag{1}$$

where K is the amplification, or $K = e_0/e_i$. In this equation, one of the parameters is resistive, the other either capacitive or inductive. Any combination which makes the Y_1Z_2 term proportional to frequency yields an integrating circuit; if this term varies inversely with frequency, a *differentiating circuit* results. The critical transitional frequency, as noted above, is given by

$$|Y_1Z_2| = 1 \tag{2}$$
FIG. 2. Integrating circuit.

These equations are satisfied for an integrating circuit with Y_1 capacitive and Z_2 resistive, or Y_1 resistive and Z_2 inductive.

6. RC Integrators. The RC integrator (Fig. 2) uses a series resistor and a shunt capacitor to produce integration. Integration occurs under conditions for which Y_1Z_2 is large compared with unity, with the result that the critical frequency must be less than a fifth of the lowest frequency to be handled by the integrator. As can be seen, Eq. (1) takes the form $1/pCR$ when $pCR \gg 1$, where the $1/p$ indicates an integration. Physically, this integration is obtained by the charge stored in the capacitor

suppressing the voltage variations which are applied to the series resistor. The integrator tends to have a constant voltage output.

7. *LR* Integrators. The *LR* integrator uses a shunt resistor and a series inductor to produce integration. As with the *RC* integrator, integration occurs when the value of Y_1Z_2 is large compared with unity. Once again, the critical frequency should be less than one-fifth of the lowest frequency to be handled by the integrator. The equivalent integration equation for the *LR* integrator takes the form $1/pGL$, where $G = 1/R$. Physically the integration is a consequence of the induced voltage (derivative effect) developed in the inductor minimizing the rapid changes of current in the shunt resistor, with the result that a constant-current output is generated for frequencies above critical.

8. Capacitive Constant-current Integrators. Integration may be obtained by the use of passive elements in conjunction with active devices as well as with passive circuits alone. Here the active device serves as a constant-current source, thereby charging and discharging a capacitor (X_L) used as a load impedance, as in Fig. 3, and producing direct integration. The main advantage of the active integrator is the greater voltage efficiency available. A signal voltage is applied to the active device for conversion into a current source. Using a pentode tube as the source with the screen by-passed to its cathode and with cathode degeneration, the current equation takes the form, based on Fig. 3,

$$i_o = g_{m1}e_i/(1 + g_{m1}R_k) \tag{3}$$

where g_{m1} is the transconductance of the tube and the other factors are defined in Fig. 3. The output voltage takes the form

$$E_o = i_o/pC \tag{4}$$

where i_o is the output current. This circuit arrangement is one of the best simple integrators for many applications. More complex, and more accurate, integrators can be obtained through the use of high-gain amplifiers with integrator circuits in the feedback paths.

FIG. 3. Active integrating circuit.

9. Inductive Constant-voltage Integrator. This integrator uses a stabilized voltage amplifier in connection with a conventional *LR* integrator to develop an output current which is the integral of the applied voltage. Its operation is identical with that of the *LR* integrator already discussed.

10. Differentiating Circuits. Circuits which offer little or no hindrance to the passage of signals having frequencies well above the critical frequency but attenuate to half for each octave below this frequency may be called differentiating circuits. In their simplest form, there are four basic combinations of *R*, *C*, *L*, and constant-voltage or constant-current sources, used in pairs, which may be used to form differentiator circuits. They are:

1. *CR* differentiators (passive)
2. *RL* differentiators (passive)
3. Inductive constant-current differentiators (active)
4. Capacitive constant-voltage differentiators (active)

The equation governing the operation of the simple differentiator (using the series-shunt circuit) is exactly the same in form as for the integrator circuit, viz.,

$$K = 1/(1 + Y_1Z_2) \tag{1}$$

To obtain differentiation, however, the Y_1Z_2 term in the denominator is inversely proportional to frequency, or takes the form

$$Y_1Z_2 \sim 1/p \tag{5}$$

The critical, or transition, frequency occurs when the YZ product has a magnitude of unity, and differentiation is obtained when the value of the product is large compared with unity, a minimum of five or more. The amplification equation then takes the form

$$K = p/A \tag{6}$$

where A is a dimensionless quotient, either $1/RC$ or R/L.

11. *CR* Differentiators. These make use of a capacitor as the series element Z_2 and a resistor as the shunt element Y_1. This arrangement permits the transmission of sharp voltage changes to the resistor, but blocks the passage of slow changes. The value of A in Eq. (6) then is $1/RC$, making Eq. (6) read

$$K = pCR \tag{7}$$

12. *RL* Differentiators. The RL differentiator has the reactance element as the shunt element, using the build-up of impedance with frequency to cause the increased output. The amplification equation takes the form

$$K = pL/R \tag{8}$$

13. Inductive Constant-current Differentiators. Differentiation can also be obtained by use of a constant-current tube with a reactance in its plate circuit which increases linearly with frequency. Such a differentiator may be assembled by use of a pentode constant-current tube having an inductance for Z_L of Fig. 3. The gain is then

$$K = g_{m1}pL/(1 + g_{m1}R_k) \tag{9}$$

where Z_L of Fig. 3 has the reactance pL.

14. Capacitive Constant-voltage Differentiators. This differentiator actually consists of a voltage amplifier followed by a CR differentiator; as a result it need not be discussed further. Its operating equation, which consists of the products of those for the two components, may be written

$$K = K_0pCR \tag{10}$$

APPLICATIONS OF INTEGRATORS AND DIFFERENTIATORS

Integrating circuits are used extensively as filters to reduce coupling from power-supply impedance and to reduce the amount of ripple and noise which can get to the input circuits of high-gain amplifiers. The RC form is particularly effective because of its ability to supply the charge storage required to provide the variable currents used by electronic circuits.
Fig. 4. Decoupled amplifier.

15. The Decoupling Filter. RC filters are commonly used between amplifier stages to minimize coupling through the impedance of the power supply, and to reduce ripple and noise. These filters can also prevent oscillation and motor-boating. A typical circuit is shown in Fig. 4.

The signal-frequency loss of the decoupling network for the high-voltage supply of an amplifier should be sufficient to make the product of the loss factor K_d in the filter and the forward gain of the amplifier K less than unity over the full range of operation if self-oscillation is to be prevented. In addition, the capacitance should be large enough to keep the voltage variation across it small compared with the output signal voltage (less than a fifth of

the output). These limiting conditions are

$$KK_d = K/\omega_1 C_f R_f < 1 \tag{11}$$

and

$$\omega_1 C_f R_L = 5 \tag{12}$$

where R_L is the load impedance and C_f and R_f are the filter components. The capacitor size C_f given in the equation is the minimum which normally can be used without introducing low-frequency distortion and phase shift. For applications requiring maximum constancy of delay, an even larger value of capacitance should be chosen, from two to five times that given by the equation.

A decoupling filter (C_sR_s in Fig. 5) may be used to limit voltage variation developed at the screen of the amplifier tube. In this application, the filter is used for two purposes, the first being to reduce the supply voltage E_{bb} and the second to keep the screen voltage sufficiently constant that screen degeneration is not introduced. The value of R_s used must be such as to reduce E_{bb} to the screen voltage E_{c2} at the average
Fig. 5. Pentode amplifier.

screen current drawn by the tube; the value of C_s should be large enough to keep the variation of the screen voltage under full signal conditions from exceeding the input voltage. (This is a rule of thumb which works out effectively.) The exact equation may be found, in terms of screen-to-plate transconductance, to reduce to the approximate form

$$G_{m2}X_{c2}/\omega_1 C_s = 0.2 \tag{13}$$

where the 0.2 has been chosen to make certain that degeneration will not alter the over-all amplification by more than a few per cent. In this equation, X_{c2}, the screen correction factor which gives the percentage of the nominal plate current drawn by the screen, has a value between 0.1 and 0.4 for most pentodes, G_{m2} is the slope of the screen voltage–plate current curve,[1] ω_1 is the radian frequency at which the low-frequency response of the amplifier is reduced by 3 db, and C_s is the screen by-pass capacitance.

The equation for the value of screen resistance required may be written as

$$R_s = (E_{bb} - E_{c2})/I_pX_{c2} \tag{14}$$

[1] Pullen, K. A., Conductance Curves Speed Pentode *RC* Amplifier Design, *Tele-Tech*, July, 1953; The Use of Screen-to-plate Transconductance in Multigrid Tube Circuit Design, *Elec. Eng.*, October, 1954.

where I_p is the average plate current, E_{c2} is the screen voltage, and X_{c2} is the screen correction factor.

The technique used for obtaining the operating screen and plate currents using the correction factors X_p and X_{c2}, sometimes called the conductance technique because it also facilitates the determination of transconductance values, is designed to give emphasis to the more important variations in the tube and to reduce to secondary status the less important relations. With pentodes, the important relations are the variation of the space current with screen voltage at fixed values of bias and the variation of the space transconductance with bias and screen voltage. These relations are presented on conductance data sheets in terms of a nominal plate current and a nominal transconductance to the plate (nominal because the value given is that which is obtained with the plate voltage twice the applied screen voltage); the nominal values are identified by the symbols I_p and G_{m1} or G_{m2}. The actual plate and screen currents and the transconductances are related to the nominal values by the following equations:

$$i_b = I_pX_p \qquad g_{m1} = G_{m1}X_p \qquad g_{m2} = G_{m2}X_p$$
$$i_{c2} = I_pX_{c2} \qquad g_{m12} = G_{m1}X_{c2} \qquad g_{m22} = G_{m2}X_{c2}$$

where i_b = instantaneous plate current
i_{c2} = instantaneous screen current
I_p = nominal plate current
g_{m1} = actual transconductance from first grid to plate
g_{m12} = actual transconductance from first grid to screen
g_{m2} = actual transconductance from screen to plate
g_{m22} = actual screen conductance
G_{m1} = nominal transconductance from first grid to plate
G_{m2} = nominal transconductance from screen to plate
X_p = plate correction factor for a given ratio of plate to screen voltage
X_{c2} = screen correction factor for a given ratio of plate to screen voltage

These definitions have been patterned after the standard IRE definitions and have been adapted as required to provide efficient organization and use. The modification of the symbols for static and limit values within the style of the IRE standard is explained in the footnote to Sec. 47.

One point to be remembered in the design of screen decoupling circuits for r-f and i-f amplifiers is that sometimes, particularly where AVC is used, the frequency ω_1 may be in the audio region instead of being about half the r-f or i-f frequency. This is because the presence of either hum or AVC in the power-supply voltage can leak into the screen circuit and, if G_{m2} changes sufficiently rapidly with E_{c2}, can actually modulate the signal being amplified, thereby establishing an oscillation.

A few other applications of simple RC integrators are listed below:

1. AVC decoupling circuits
2. Filters for use with detectors
3. Power-supply filters

16. Integrators with F-m Transmitters. If a phase-modulation transmitter is modulated with the integral of the desired communication information, the over-all result will be the production of a frequency-modulated wave. The frequency stability which can be obtained with such a transmitter greatly surpasses that of ordinary f-m type units. The integrator must be designed to operate efficiently and reasonably accurately over a frequency range of at least 1,000 to 1, with the result that the RC integrator must have carefully selected components. The capacitor must have a high Q and a small leakage over the frequency range, and the resistor must be stable and have a low shunt capacitance.

A preemphasis circuit is often used to permit an improvement of the over-all signal-to-noise ratio of the system. Possible ways of introducing the required preemphasis are the use of a differentiator to offset the integration, a by-pass circuit which makes the integrator partially ineffective above a selected high audio frequency, and the use of a zero-phase-shift circuit which has negligible loss below the audio range, a rapidly

increasing loss with frequency to the selected high frequency, and a constant loss above this frequency. The zero-phase-shift circuit is described in Sec. 26.

17. Uses in Wave Shaping. Integrator and differentiator circuits are very effective for wave shaping, since they can be used to suppress either the high- or the low-frequency components of an applied signal as is required. The integrator tends to emphasize the sine wave corresponding to the lowest-frequency component in the signal, converting a square wave first into a triangular wave, a triangular wave into a parabolic wave, etc., as shown in Fig. 6. The differentiator, on the other hand, emphasizes the higher-frequency components at the expense of the lower, converting a square wave into a pulse approximating a delta function, and on repeated differentiations creating waves somewhat as shown in Fig. 7. The number of zero-axis crossovers from each step of the square wave with a string of differentiators is one less than the number of differentiator circuits.
FIG. 6. Effects of integration on wave form.
FIG. 7. Effects of differentiation.
FIG. 8. *RC* frequency-selection circuit.

18. Integrators vs. Differentiators. In practice, integration usually can be accomplished with more nearly ideal results than differentiation for the following reasons:

1. The critical frequency usually can be placed well below the lowest required frequency with the integrator; it cannot always be placed above the highest with the differentiator because of the absence of an upper limit in the Fourier spectrum of an ideal wave form.
2. A high-frequency spectrum limitation on the incoming signal with a differentiator is as destructive to wave shaping as too low a critical frequency would be. A corresponding condition seldom occurs with integrator circuits.
3. Circuits for the improvement of integration linearity are simpler to design and build than are the corresponding circuits for differentiation.

Both integrator and differentiator circuits are essentially frequency-selection circuits. Integrators, when used as power-supply or decoupling filters, are intended to pass a narrow band of frequencies adjacent to zero frequency. Differentiator circuits are used as high-pass filters in the coupling networks in amplifiers. Consequently, the design of the corresponding circuits has to be coordinated if the best possible performance of the amplifier is desired.

Combinations of differentiator and integrator circuits can be used either for rejection or for emphasis of narrow bands of frequencies. Band rejection is accomplished by paralleling an integrator and a differentiator; the critical frequency for the differentiator should be appreciably higher than that for the integrator. Band pass may be obtained by having the critical frequency of the integrator higher than that of the differentiator and connecting the networks in series. A circuit showing a slight modification of such an arrangement as used in an oscillator is shown in Fig. 8. Most

of the Wien bridge type of *RC* oscillators make use of a combination which behaves as an integrator and a differentiator in series, the critical frequencies of each being chosen to give the required frequency characteristics.

RLC CIRCUITS

The *RLC* circuit in one of its many combinations is probably the most flexible of all frequency nonlinear or frequency-selective circuits. An *LC* circuit, if it could be made of lossless components, would be an optimum device for taking either the second integral or the second derivative of an applied wave form; since, however, the loss in the inductance is sufficient to make the circuit nonideal in behavior, the *RLC* circuit is used primarily for its frequency-selection properties and as a filter for power supplies.
FIG. 9. Resonant circuit consisting of dual elements.

19. Phenomena in *RLC* Circuits. The operating characteristics of an *RLC* circuit by itself are determined by shock or transient excitation. If two low-loss circuits (or circuits having a dissipation per cycle small compared with the stored energy) which are duals of one another are interconnected with energy stored in one of them, as in Fig. 9, a transient vibration, damped in nature, commences and continues until all the stored energy is dissipated. (Two networks are duals if the susceptance of one is proportional to the reactance of the other. Resistive and conductive components need not be considered.) The energy in the one circuit is transferred to and stored in the other and then returned in a cyclical manner. In the strictest sense of the word, the true resonant frequency of the system is controlled by this free and controlled energy interchange. If the system is driven the response of the network depends on both the component arrangement and the way in which the circuit is excited.

FIG. 10. Series *LC* circuit.

20. Driven *RLC* Circuits. Two principal forms of driven *RLC* circuits are commonly used—in fact, most frequency-selection circuits for *LC*-type oscillators can be represented as the one or the other. One of these is the series- and the other is the parallel-resonant circuit. Each of these circuits may be excited in a variety of ways, and each way causes the circuit to appear to have its own special frequency of maximum response. An example in terms of the series-resonant circuit is given below.
The circuit of Fig. 10 is used primarily as a trap in most electronic applications other than oscillators. It has the disadvantage of having a low impedance at resonance, with the result that it gives a low voltage output with ordinary conductance-controlled devices such as tubes and transistors. Its electrical characteristics make it particularly useful with voltage output, current input, or resistance-controlled devices.

FIG. 11. Typical plot of Z vs. ω for series-resonant circuit.

The general shape of the impedance curve for a simple series-resonant circuit takes the form shown in Fig. 11. Its equation is

$$Z = \sqrt{R^2 + (\omega L - 1/\omega C)^2} \quad (15)$$

Under constant-voltage excitation with the current $I = E/Z$, a maximum current will flow when the net reactance is zero.

Although the curves for Z and I are symmetrical when plotted on a logarithmic

frequency scale, the voltages in the circuits as actually used seldom show a corresponding symmetry. The voltage is developed by the current flowing through either an inductive or a capacitive reactance. Because of the symmetry of the current and the asymmetry of the reactance, the voltage is asymmetrical, as can be seen in Fig. 12.

FIG. 12. Typical variation of X_L, I_L, and E_L with ω.

The parallel-resonant circuit (Fig. 13*a*) is ideal for use with tubes and transistors operating under normal conditions because of their current-output characteristics. Parallel circuits may be excited either by a constant current or through magnetic coupling (which in effect couples a voltage source in series with the coil, giving the equivalent of constant-current excitation), or through a tap on the coil or capacitor as in Fig. 13*b* or *c*.

FIG. 13. Typical coupling circuits.

If the parallel-resonant circuit is excited from a constant-voltage source, either magnetic coupling or an inductive or capacitive tap is required to get the circuit excited in series. Then the output may be taken in parallel across either the coil or the capacitor as indicated.

21. Wave Filters. In addition to the normal applications of *LC* elements in tuned circuits, they may also be used in wave filters. In simple filters (constant-*K* type), the series element *Z* and the shunt element *Y* are dual elements or dual combinations of elements. When terminated in the proper resistances, such filters pass signals over some ranges of frequencies and reject them over others. Figure 14 and Table 1 indicate the characteristics and the controlling equations of the commonest types. Low-pass filters of the constant-*K* type are often used for power-supply filters.

FIG. 14. Constant-*K* wave filters.

The value of the terminating impedance as a function of frequency that is required by the simple wave filter often is not sufficiently constant to satisfy many applications. Consequently, a filter section called the *M*-derived section is commonly used (Fig. 15).

Table 1. Constant-K Wave Filters

Type	Z_1	Y_2	ω_1	ω_2	ω_0	ω_C	Z_T
Low.......	ωL	ωC	0	$\frac{2}{\sqrt{LC}}$	....	......	$\sqrt{\frac{L}{C}}$
High.......	$\frac{1}{\omega C}$	$\frac{1}{\omega L}$	$\frac{1}{2\sqrt{LC}}$	∞	....	......	$\sqrt{\frac{L}{C}}$
Band pass..	$\omega L - \frac{1}{\omega C}$	$K\left(\omega C - \frac{1}{\omega L}\right)$	$\frac{1}{\sqrt{KLC}}(\sqrt{1+K} - 1)$	$\frac{1}{\sqrt{KLC}}(\sqrt{1+K} + 1)$	$\frac{1}{\sqrt{LC}}$	$\frac{2}{\sqrt{KLC}}$	$\sqrt{\frac{L}{KC}}$
Band rejection	$\frac{\omega L}{\omega^2 LC - 1}$	$K\left(\frac{\omega C}{\omega^2 LC - 1}\right)$	$\frac{1}{\sqrt{KLC}}(\sqrt{1+K} - 1)$	$\frac{1}{\sqrt{KLC}}(\sqrt{1+K} + 1)$	$\frac{1}{\sqrt{LC}}$	$\frac{2}{\sqrt{KLC}}$	$\sqrt{\frac{L}{KC}}$

ω_1 = angular frequency for cutoff at lower limit
ω_2 = angular frequency for cutoff at upper limit
ω_0 = mid-angular frequency for band-pass filters
$\omega_C = \omega_2 - \omega_1$
Z_T = theoretical terminating impedance
K = arbitrary constant which affects band width and impedance

These sections are also used to increase the rejection at frequencies near the band edge where sharp cutoff is required. The basic equations for low- and high-pass filters of the M-derived type are included in Table 2.

As can be seen from the two tables, wave filters may be used for three principal applications, namely low-pass, high-pass, and band-pass. Only rarely are band-rejection filters required. Low-pass filters may be used as delay lines for video pulses, and band-pass filters for r-f carrier pulses. The delay characteristics (phase vs. frequency) for such filters are discussed briefly below under phase nonlinearities.
FIG. 15. M-derived half sections.

22. Tuned Circuits for Amplifiers. The design of tuned circuits for r-f and i-f applications is simple, but generally rather poorly understood. Two variables are available for adjusting these circuits, the reactance and the Q. The Q controls the band width, and the product of the reactance and the Q controls the impedance level, amplification K, and the stability. The equations are

$$Z = X_c Q \tag{16}$$
$$K = -g_{m1} Z \tag{17}$$

where Z is the resonant impedance of the tuned circuit. The value of K should be chosen sufficiently small that the product of K by the feedback gain K_f is less than unity (Fig. 16). The value of K_f should be less than

$$K_f = 1/\omega C_f Z \tag{18}$$

where C_f is the feedback capacitance as shown in Fig. 16. Equations (17) and (18) give a limiting value for Z in the form

$$Z = \sqrt{1/\omega C_f g_{m1}} \tag{19}$$

Table 2. M-derived Low- and High-pass Filters

Type	Z_1	Y_2	ω_1	ω_2	ω_∞	Z_m
1. Low.......	$m\omega L$	$\frac{4m\omega C}{\omega^2(1 - m^2)LC - 4}$	0	$\frac{2}{\sqrt{LC}}$	$\frac{\omega_2}{\sqrt{1 - m^2}}$	$\sqrt{\frac{L}{C}}$
2. Low.......	$\frac{4m\omega L}{\omega^2(1 - m^2)LC - 4}$	$m\omega C$	0	$\frac{2}{\sqrt{LC}}$	$\frac{\omega_2}{\sqrt{1 - m^2}}$	$\sqrt{\frac{L}{C}}$
3. High.......	$\frac{m}{\omega C}$	$\frac{4m\omega C}{4\omega^2LC - (1 - m^2)}$	$\frac{1}{2\sqrt{LC}}$	∞	$\omega_1\sqrt{1 - m^2}$	$\sqrt{\frac{L}{C}}$
4. High.......	$\frac{4m\omega L}{4\omega^2LC - (1 - m^2)}$	$\frac{m}{\omega L}$	$\frac{1}{2\sqrt{LC}}$	∞	$\omega_1\sqrt{1 - m^2}$	$\sqrt{\frac{L}{C}}$
ω_∞ = angular frequency for maximum attenuation
m = parameter which controls constancy of terminating impedance and frequency of maximum attenuation. A value of 0.6 gives best uniformity of the filter terminating impedance
Z_m = theoretical terminating impedance of filter

Actually, if the amplifier has only one or two stages, Z may sometimes be somewhat greater than the value given by Eq. (19) since the effect of phase has been neglected entirely. In multistage amplifiers, however, phase shifts from random causes can give with comparative ease the required phase for oscillation.

23. *RLC* Circuits as Coupling Devices. Inductive coupling circuits for coupling to or from coaxial lines may be either tuned or untuned (Fig. 17). Either series- or parallel-tuned circuits may be used; usually the Q of the coupling circuit is made low to broad-band the coupling circuit. Since the adjustment of any of these types of coupling loops may be accomplished with little difficulty if proper precautions are taken, the next few paragraphs indicate how advantage can be taken of the broad optimum which is available.

FIG. 16. Tuned amplifier with capacitive feedback.

As tuned circuits are coupled to one another, more and more of the energy in the excited circuit is withdrawn through magnetic coupling by the coupled circuit, reducing effective Q of each circuit. As a result, when critical coupling is reached, the optimum voltage coupling is reached, and the tuned circuits "double-hump" as the coupling is tightened further. This double-humping effect results in a limitation of the transformation ratio by developing an area between the two peaks in which the ratio is somewhat less than maximum. The two humps bracket the original operating frequency. Tightening the coupling toward unity moves one of the peaks toward zero and the other toward infinite frequency, giving an area of relatively uniform response in the middle.

The effective use of a tuned circuit as a coupling element requires the design to be such that the internal loss is small, and at the same time broad-band operation makes necessary a high over-all loss from the load. Consequently, the coupling circuit should have an unloaded Q in excess of 50, and a loaded Q between 2 and 10. The equations for use in the design of series-tuned coupling loops under these conditions are

$$\begin{array}{lll} Q_L = X_c/R_t & 2 < Q_L < 10 & Q_U > 50 \\ \omega^2 LC = 1 & K = \sqrt{Q_L Q_T} & \end{array} \qquad (20)$$

where R_t is the impedance of the load connected to the coupling circuit, X_c is the capacitive reactance of the series capacitor, Q_L and Q_U are the loaded and unloaded Q values for the loop, respectively, Q_T is the Q value for the tuned circuit, and K is the coefficient of coupling. For the shunt-tuned coupling circuit, only the equation for the loaded Q value is changed:

$$Q_L = R_t/X_c \qquad (21)$$

After the proper L and C values have been selected and the circuit assembled, the final adjustment is to tighten the coupling between the main tuned circuit and the coupling circuit until the desired operating characteristics are obtained.
FIG. 17. Inductive coupling circuits.

A plot of the voltage-transfer characteristic as a function of the reactance of the untuned loop shows that a broad maximum occurs when its reactance X_L is approximately equal to R_t. This maximum is sufficiently broad that extensive charts can be prepared to indicate the relation, but frequently the charts are not needed if the maximum condition is used for design purposes. (The existence of the maximum may be shown mathematically.)

If the coupling between an untuned loop and a tuned circuit is gradually tightened, characteristics much similar to those of the tuned loop are noted. First the voltage transfer rises, finally levels, and then changes but little. The concept of critical coupling applies approximately with the untuned loop since Q_L now is taken as unity. (It is designed so that $X_L = R_t$.) The coupling equation becomes

$$K = \sqrt{Q_T} \qquad (22)$$

Physically, the process is as follows: first, as the coupling is tightened, transfer rises, but the loading from the coupled circuit is small compared with the damping of the tuned circuit itself. As the coupling increases, however, the damping due to the coupling link finally becomes equal to the damping in the tuned circuit; then the Q of the tuned circuit drops as coupling is increased, keeping the over-all transfer constant.

PHASE NONLINEAR CIRCUITS

The phase characteristics of signals are of rapidly growing concern, partly because of their importance in television, and particularly in color TV, and also because of their importance in such areas as pulse circuitry, instrumentation systems, and computing machines. Ideally, in the processing of signals, the changing of frequency response without changes of phase, and vice versa, would provide the most effective method of compensation. Unfortunately, however, it is almost impossible to change the frequency response without altering the phase also. Some of the methods of

controlling phase and frequency relations are discussed after an examination of the basic relations to determine the problems.

24. Linear-phase Conditions. A linear-phase circuit is one which introduces a constant delay of all frequencies which it passes. Since the delay is seldom zero, the phase shift of a constant-delay circuit should be a linear function of frequency over the entire operating range. The construction of a device capable of providing a constant delay yet, at the same time, altering the frequency characteristics of the wave being transmitted appears to be a problem similar to the one of reducing the entropy of a closed system: present knowledge seems to indicate that it may never be solved for the general case. The availability of a device capable of providing constant delay and frequency compensation simultaneously would improve the signal-to-noise ratio in pulse systems, since it would simplify the separation of a pulse in terms of its lower-frequency components.

FIG. 18. Constant-amplitude variable-phase circuit.

25. Phase-shift Networks. Two types of phase-shift devices are available to the engineer—the frequency-dependent variable-delay network, and the frequency-independent variable-delay network. Both these types of circuits find frequent use. The group of frequency-dependent variable-delay networks includes almost all the commonly used networks found in electronics. Such circuits as *RC* and *CR*, *RL*, and *RLC* all show a characteristic which has variable phase shift and variable delay if examined over a sufficiently wide range of frequencies. Only a limited number of circuits, those which have input-output relations similar to that of the circuit shown in Fig. 18, in which the output may be represented as the radius vector of a semicircle as a function of frequency, can provide controllable delay with negligible change of frequency response.

Simple circuits having a variable delay may be grouped into four basic categories, namely, those showing a net phase change of zero degrees in two frequency ranges, these ranges being separated by an area of transition; those showing 90-deg shift; those showing 180-deg change in phase shift over a narrow range of frequencies; and those showing a phase-shift difference of approximately 90 deg over a range of frequencies, but at the same time having a uniform amplitude response as a function of frequency.

26. Zero-net-phase-shift Networks. Networks which provide a net phase change of zero over two ranges of frequency but which have a phase shift other than zero between the two ranges are typified by those shown in Fig. 19. These circuits have a gain K_1 over one range of frequencies, K_2 over a second range of frequencies, with a net phase shift of zero within the ranges. Such circuits find wide application in the compensation of feedback and servoamplifiers because of the attenuation which can be introduced without at the same time introducing troublesome phase shifts, shifts sufficient in many cases to cause oscillation. The use of these circuits often permits the loop amplification of an amplifier to be increased by as much as 20 db without development of instability. In terms of components Z_1, aZ_1, and jX_2, the gains are tabulated in Table 3.

FIG. 19. Zero-degree-phase attenuation circuits.

A network having properties similar to those of Fig. 19*a* is shown in Fig. 19*b*. With the definitions indicated, the equations applying to Fig. 19*a* and *b* are identical. The equation for amplification is

$$K = [a(1 + a) + u^2 + ju]/[(1 + a)^2 + u^2] \qquad (23)$$
Table 8. Zero-degree Phase-shift Circuit

Frequency function	Gain	Phase, deg
$u \ll 1$	$\frac{a}{1+a}$	0
$u = \frac{X_2}{Z_1}\left(\text{or } \frac{b_2}{Y_1}\right) \approx \sqrt{1+a^2}$	$\frac{a(1+a)+u^2+ju}{(1+a^2)+u^2}$	$\frac{u}{a(1+a)+u^2}$
$u \gg 1$	1	0

Z_1 = attenuating impedance, normally a resistance
aZ_1 = loss impedance, normally a resistance
a = ratio of shunt to series resistance
X_2 = switching reactance, usually capacitive
Y_1 and aY_1 = conductances corresponding to aZ_1 and Z_1, respectively
b_2 = switching susceptance corresponding to X_2
u = parameter which is a function of frequency. It has values of X_2/Z_1 in Fig. 19b, b_2/Y_1 in Fig. 19a
ϕ = phase angle between input and output

The phase shift ϕ may be determined from

$$\tan \phi = u/[a(1 + a) + u^2] \tag{24}$$

and the maximum phase shift from

$$\phi = \arctan 1/[2\sqrt{a(1 + a)}] \tag{25}$$

27. 180-deg Circuits. Circuits capable of producing a phase shift of 180 deg over an extended range of frequencies introduce no effect on the applied wave form other than inverting it, with the result that variable delay is not introduced. Circuits which introduce approximately zero degrees phase shift over one range and 180 deg over an adjacent range with a transition between, however, do introduce a variable delay. An *RLC* circuit is capable of producing such an effect when properly excited. In such a circuit (Fig. 20) the voltage produced at the output is shifted approximately 90 deg at the frequency for which $\omega^2 LC = 1$, approximately zero degrees for frequencies appreciably less, and approximately 180 deg for frequencies appreciably greater. Such circuits are used only at very high frequencies, however, as at low frequencies simple transformers and electronic phase inverters are usually better.
Fig. 20. *LC* filter.

28. 90-deg Circuits. Circuits, such as integrators and differentiators, which shift the phases of frequency components by approximately 90 deg when integrating or differentiating, cause a significant change in the appearance of the wave (Fig. 21). The change is due partly to the phase shift and partly to the change in amplitude response. Further data may be found in Secs. 4 and 10.

29. Wide-band 90-deg Circuits. Wide-band circuits designed to produce 90 deg difference in phase in the outputs from two channels are used extensively in some single-side-band (SSB) modulation systems. The phase-shift technique uses two audio signals which are alike except for the 90-deg phase difference, and two carrier signals which also have a 90-deg phase difference. These signals are introduced into two balanced modulator circuits (Sec. 68) (each modulator receives one of the audio signals and one of the carrier signals). After modulation the two output signals are added to eliminate either one or the other of the side bands. Reversing the polarity of one of the modulation inputs will permit shifting from one side band to the other.

A form of all-pass network normally is used in the production of wide-band phase-shift circuits as used in SSB. The basic circuit is shown in Fig. 22. A group of these circuits are made up in two chains *A* and *B* with the capacitances in the chains adjusted so that a phase angle of approximately 90 deg is developed between the

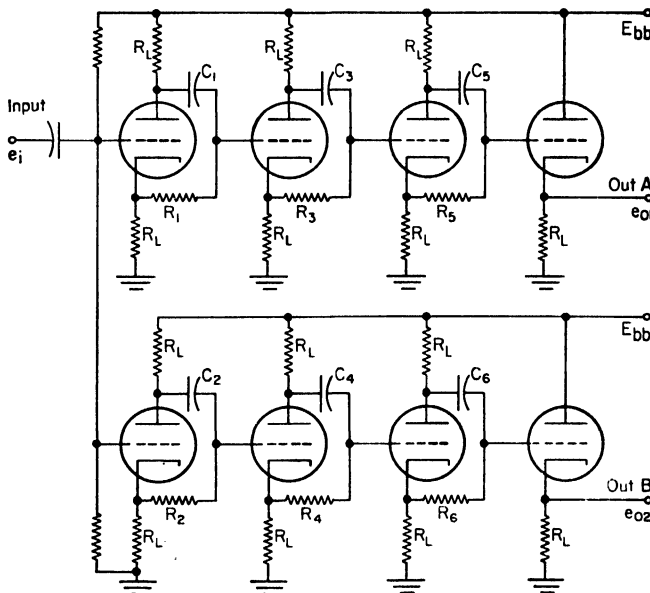
respective frequency components in the output waves from the two chains. The differential phase shifts within any pair of circuits may be between 10 and 30 deg, depending on the band width and the precision required in the phase shift. The best procedure for adjusting these circuits is to plot the phase difference as a function
Fig. 21. Effect of phase on wave form.


Fig. 22. Wide-band quadrature circuit.

of frequency, and then adjust the values of some of the capacitances to provide the required characteristics.

30. Minimum- and Nonminimum-phase Networks. Minimum-phase networks normally include those which are constructed from passive devices, R, L, C; however,

certain circuit configurations which do not contain active elements may possess nonminimum-phase characteristics. The principal distinguishing characteristic between the two types of circuits is in the positions of the zeros of transmission in the expression for the Laplace transform of the transfer admittance for the network; these zeros may be either on the imaginary axis or in the right-half plane for a network with nonminimum phase. Wide-band all-pass networks are possibly one of the best examples of nonminimum-phase networks.

All-pass networks have a set of transmission zeros in the right-half plane at points which are mirror images with respect to the imaginary axis of the poles of the Laplace transform of the network transfer function. The result is that the network passes all frequencies with a constant signal amplitude, and introduces phase shifts as a function of frequency which can be used for compensating for undesired phase shifts.

31. Conditions for Constant Delay. Constant delay may be obtained with most types of coupling circuits if they are used in the appropriate ranges. Since the maintenance of constant delay is frequently of great importance the next few paragraphs discuss the conditions required to obtain constant delay in some of the more common circuits. More information may be found in books and articles on wave filters and delay lines, on telephone and television circuits, and on similar subjects.

Constant delay with RC and RL circuits may be obtained only over a narrow range of frequencies for which the amplification as a function of frequency is almost exactly constant. The region of constant delay extends to a maximum phase shift of less than 10 deg, or a change of amplification of approximately 2 per cent. For low-pass circuits, the maximum frequency to which an approximately constant delay may be obtained is approximately one-sixth of the frequency for which $R = X$, and for high-pass circuits, the minimum frequency is approximately six times that at which $R = X$. A factor of either 10 or one-tenth is normally used in the design of television circuits to make certain that the phase and flatness specifications are fulfilled.

R-f and i-f circuits are also subject to variable delay. Depending on the number of amplifier and selection stages being cascaded when constant delay is required, the total phase shift permitted per stage may range from 1 to 10 deg per selection circuit, depending on the phase accuracy required and on the total number of amplifiers and selective circuits in the over-all system. The error per selective circuit may be approximated by adding the successive differences between the phase angle in radians and the sine of that phase angle for each successive circuit involved. In other words, the error for one stage is

$$E \approx \theta^3/6 \tag{26}$$

where θ is the phase angle in radians. For n stages, the equation may be written

$$E \approx \sum_{i=1}^{n} \theta_i^3/6 \tag{27}$$

The differential delay for television signals should be kept to a fraction of a microsecond if a clear and accurate picture is desired. For color, true color registry requires that the differential delay be less than 50 deg at 3.85 Mc, or less than 0.1 μsec.

32. Variable Delay in Transmission Lines. Any type of transmission line or delay line is subject to delay distortion if the effective propagation velocity varies with frequency. The conditions for constant delay in any transmission line are that, on a per-unit-length basis, the following relation between the parameters exists:

$$R/L = G/C \tag{28}$$

where R and L are the series R and L per unit length, and G and C are the shunt conductance and C per unit length. Further data on this problem may be found in any of the many texts on design of telephone circuits and on design of wave filters.

33. Practical Effects of Variable Delay. The maintenance of constant delay is of much greater importance than the maintenance of a uniform frequency-response char-

acteristic in many electronic systems. The variation of delay with frequency can excite ringing within a circuit and can produce noticeable transients and changes of appearance and timbre. Circuits which are compensated to give a flat frequency response tend to overshoot and to ring, whereas circuits which are compensated to a flat phase (constant delay) characteristic do not. A phase-compensated r-f or i-f amplifier system has a monotonic decay of amplification on either side of the peak frequency (a Bessel[1] response), rather than an equal ripple or related type of response across the pass band.

Constant delay is important in audio as well as video applications. DeRosa[2] has shown by synthesizing tones that the timbre of a combination is dependent on the phase relations of the harmonics. In addition, the phase transients can produce chirps and buzzing or rattling often noticed in poorly designed high-fidelity equipment.

Systems which use the comparison of the phase of sine-wave signals are highly sensitive to the effects of variable delay, particularly if a combination of several frequencies is used in the measurement. The phase error resulting from each individual measurement must be kept small enough so that there is no ambiguity in reading one phase with respect to another. (In other words, the error on one frequency should be less than one-third of the phase shift corresponding to one cycle of phase of the next higher frequency.) Often it is possible to get the required accuracy in the circuitry, but errors due to propagation vagaries or multipath effects may be large enough to render a phase-measuring system of little use.

Variable delay in the r-f and i-f systems for conventional a-m communication systems seldom introduces difficulty because of the redundancy of the information being transmitted. The variation of the delay has the effect of introducing frequency modulation into the signal and reducing the over-all percentage of modulation. In addition to the reduction of the percentage of modulation, the variation of delay introduces distortion into the modulation signal.

A similar conclusion may readily be drawn for the effect of variable delay on an f-m communication system. The band width normally used with f-m systems is considerably wider than that used with a.m., with the result that internal-delay problems may be somewhat more serious than with a.m. Variable delay once again reduces the modulation index and introduces distortion as a result of conversion of part of the f-m signal to a.m.

The effect of variable delay on pulse-modulated signals has largely been neglected in the literature. If the Fourier spectrum of a pulse is examined, however, it can be shown to be the summation of a small amount of each of a long series of harmonically related components. Since the form of the pulse is affected by comparatively small changes in the phase relations of these harmonic components, variable delay can be very important, particularly as the duty-cycle μ is reduced. The equation for the wave form of a pulse in terms of its harmonics may be written

$$E_{(x)} = k\left(\mu + \frac{2}{\pi}\sum_{n=1}^{\infty}\frac{\sin \pi n\mu \cos nx}{n}\right) \tag{29}$$

where x is the radian angle corresponding to time delay within the period of repetition, n is the order of the harmonic, and the pulse is symmetric about the point $x = 0$. Since the ratio $[(\sin \pi n\mu)/\pi n\mu]$ has the approximate value of unity for all values of n such that $n\mu$ is less than $\pi/6$, for values of μ of approximately 0.01 the magnitudes of each of the harmonic components up to the fiftieth are nearly equal. Evidently, small errors in the phase of the different components of the wave can cause considerable loss of recognizability in pulsed signals, particularly when the duty cycle is short.

Variations in the delay in circuits, particularly in systems which utilize large amounts of feedback, can easily make possible oscillation at a frequency which is

[1] Weinberg, L., Modern Synthesis Network Design from Tables, *Electronic Design*, **4** (18–21), Sept. 15, Oct. 1, Oct. 15, and Nov. 1, 1956.
[2] DeRosa, L. A., Phase Distortion in Audio Systems, IRE National Meeting, 1948.

determined by the delay. Conventional open-loop tests on a circuit will show the existence of critical delay conditions only if the elements which provide the abnormal delay are part of the loop in the form in which it is tested. The introduction of a loss network of the zero-degree-phase type can reduce the loop gain at the critical frequency, thereby stabilizing the system.

CIRCUITS WITH AMPLITUDE NONLINEARITY

34. Basic Operation. The discussion in the following sections, with the exception of Secs. 79 to 85, is directed to applications in which the variation of the derivative of the output current with respect to the input voltage (the transfer function) is intentionally made large to take advantage of the resulting multiplicative properties of the circuit. If, for example, the function relating the output current to the input voltage,

$$I = F(E) \tag{30}$$

is expanded in a Taylor series about the point E_0, and the variable $E - E_0$ is taken to be e_i and the variable $I - I_0$ to be i_0, it may be written as

$$i_0 = F'(E_0)e_i + F''(E_0)e_i^2 + \cdots \tag{31}$$

The first term in this power-series expansion expresses the conditions for linear operation at the point (E_0, I_0), whereas the remaining or nonlinear terms express what might be called the multiplicative properties of the device.

35. Multiplicative Action and LTV Circuits. Multiplicative action may be obtained in at least one other way, namely, by making the function F' variable under the control of some voltage other than E_0. If F' is such a function, then its value is dependent on the variation of an external parameter E_c, giving, when e_i is sufficiently small, a circuit whose behavior is linear for any fixed value of E_c, but whose properties change markedly with the magnitude of E_c. Such a circuit may be called a *linear-time-variant* (LTV) circuit.

In many applications the two types of circuits, namely, nonlinear and linear-time-variant, may be used interchangeably. Each, however, has its own special advantages. Since most time-variant circuits can be made to behave as nonlinear circuits by substituting e_i for E_c, the circuitry for all is discussed under nonlinear circuits, and the special advantages of time-variant circuits are described separately.

USES OF NONLINEAR CIRCUITS

Nonlinear circuits are especially useful in the following applications which are commonly encountered in electronics:

1. Detectors
2. Limiters and clamping circuits
3. Mixers
4. F-m detectors
5. Modulators
6. Pulse shaping and forming circuits
7. AVC circuits

In each of these applications, nonlinearity is intentionally introduced to make possible the required action. Since distortion and nonlinearity are essential to these devices, some data on the calculation of the characteristics of nonlinear devices are included in Secs. 79 to 85.

36. Detection. Detection is the process of removing desired information from a composite signal which conveys it through a communication or a processing system. The system may be a radio receiver of any type, a chopper-stabilized amplifier or power supply, a servo system, or any other of a variety of devices. The conventional a-m detector is discussed first to show how nonlinearity brings about the desired changes.

The amplitude-modulation detector separates the intelligence conveyed by the

variation of the amplitude of a carrier from the carrier itself through the use of the nonlinearity of the amplitude response of the detector. As was shown in Sec. 34, the output of a network may be expressed in terms of its input through the equation

$$i_0 = F'(E_0)e_i + F''(E_0)e_i^2 + F'''(E_0)e_i^3 + \cdots \tag{31}$$

The derivatives of the function F may be replaced by the conductance and its derivatives:

$$F^{(n)} = g_{(n-1)} \tag{32}$$

If, then, a voltage of the form $E\left(1 + \sum_{i=1}^{n} K_i \sin \omega_{mi}t\right) \sin \omega_c t$ is substituted for e_i, the output current, neglecting carrier frequency components (ω_c and $2\omega_c$), is

$$i_0 = E^2 g_{m1} \left\{1 - \sum_i^n K_i \sin \omega_{mi}t + \sum_i^n \sum_j^n K_i K_j [\cos (\omega_{mi} - \omega_{mj})t - \cos (\omega_{mi} + \omega_{mj})t]\right\} \tag{33}$$

Since the double-summation term represents the distortion and intermodulation terms, the square-law detector does not have satisfactory characteristics for received signals having values of K_i greater than 0.1. An ideal detector will provide rectification without introducing a double-summation term.

37. The Piecewise-linear Detector. One form of detector which is free of the double-summation term is known as the piecewise-linear detector, a detector which, with positive signal voltage, has one fixed value of g and, for negative input, a different value, with a sharp change of the value of g occurring between the two states when the signal voltage approaches zero (Fig. 23). With such a detector, more current is passed per volt of applied signal with one polarity than the other, with the result that the average d-c current after passage through the device is no longer zero.
FIG. 23. Piecewise-linear circuit.

Since the higher-order terms g_j, where j is greater than unity, can and should be zero, no multiple-summation terms are present, and the intermodulation distortion is reduced. The diode detector is the simplest example of a device having piecewise-linear characteristics for large input signals.

38. The Diode Detector. The diode detector makes use of the unidirectional, or unilateral, characteristics of crystal and vacuum diodes to produce an output voltage which is proportional to the modulation level. The operating equation may be written as
FIG. 24. Equivalent diode circuit, series diode.

$$i_0 = [g/(1 + gR_L)]e_i \tag{34}$$

where g is the conductivity of the device and R_L the terminating impedance (Fig. 24). Assuming that the two values of conductance are g_f and g_r and solving for the value of R_L which will give the maximum output gives

$$R_L = 1/\sqrt{g_f g_r} \tag{35}$$

If the signal source has appreciable internal impedance, it should be included in g_f and g_r, giving

$$R_L = 1/\sqrt{(1 + g_f R_i)(1 + g_r R_i)/g_f g_r} \tag{36}$$

where R_i is the internal impedance of the source. When the two products in the numerator of the function under the radical are large compared with unity, the required value of R_L exactly equals R_i, indicating that the required load impedance equals the input impedance, and the diode may be ignored from the circuit point of view. Consequently, at least g_rR_i, and if possible both g_fR_i and g_rR_i, should be small compared with unity.
Fig. 25. Equivalent diode circuit, shunt diode.

When the source impedance R_i is sufficiently large (constant-current conditions) no rectification is obtained with the series diode; the diode then should be connected in shunt, and the source impedance should be large compared with the load impedance (Fig. 25). The correct value of load impedance is given by Eq. (35).

39. The Push-Pull Diode Detector. The push-pull diode detector (Fig. 26) generates appreciably less harmonic distortion than the single diode because of the full-wave rectification obtained. It is particularly valuable when low distortion is required in extracting the modulation from a low-frequency i-f signal. The full-wave rectification in effect doubles the carrier frequency, making the distortion half or less than that otherwise introduced, partly because of the higher critical frequency which may be selected for the output low-pass filter, and partly because of the larger number of data points defining the output signal. The design of a push-pull detector is based on the same equations as the single-diode detector, the only difference in the circuitry being the center-tapped transformer required to provide the input signal.
Fig. 26. Full-wave diode circuit.
Fig. 27. Grid-leak detector.

40. The Grid-leak Detector. The grid-leak detector (Fig. 27) has, under small-signal conditions, a characteristic which is essentially piecewise linear, one in which one section is nearly of zero length, with the other having an amplitude approximately equal to the peak-to-peak amplitude of the signal being detected. The portion of approximately zero length introduces clamping, making possible very efficient detection of weak signals through the amplification of the main portion of the signal. Since, however, the linearity of a tube used as a grid-leak detector is poor if the input signal has an amplitude over 0.2 to 0.3 volt, this detector is seldom used in present-day equipment.

The grid-leak detector clamps the applied signal by grid rectification of the most positive portion of the signal, thereby producing an average bias which is approximately equal to half the peak-to-peak signal amplitude. This average bias varies with the modulation or the over-all instantaneous amplitude of the modulated wave, producing a changing average plate current in accordance with the original modulation. Amplification and distortion may be estimated either by standard techniques or by conductance techniques (Sec. 85).

41. The Power Detector. The power or plate detector (Fig. 28*a*) uses a tube operated near plate-current cutoff to take advantage of the approximate square-law characteristics of the tube. It has fallen into disuse except for applications in which an approximate power or rms voltage measurement is required.

The suitability of any tube for use as a square-law detector may be determined by examining the linearity of the variation of the small-signal amplification from cutoff

to zero bias along the load line used. The plot of amplification as a function of bias is better than a plot of output current because of the tendency of the plot of current vs. bias to integrate or average out the variations (Fig. 28*b*).

42. The Infinite-impedance Detector. The infinite-impedance detector provides linearity at least equal to that of the diode detector. Because of the large amount of inherent degeneration, an almost ideal piecewise-linear characteristic is available in the infinite-impedance detector (Fig. 29). As can be seen from Fig. 30, the correct bias for proper operation of this circuit is that value which establishes the static operating point at the mid-point of the transition region; otherwise serious distortion may be introduced with high percentages of modulation. Since the correct bias is almost equal to the value required to cut off the plate current, a fixed bias of
FIG. 28. Power (square-law) detector.
FIG. 29. Infinite-impedance detector.
FIG. 30. Gain of infinite-impedance detector.

the required magnitude should be introduced experimentally for each tube if accuracy of rectification is of critical importance. The approximate value may be found from the plate-characteristic curves for the tube used.

The output capacitance used with the infinite-impedance detector is used to smooth the output modulation and to cut off the cathode current of the tube during all but the peak of the conduction cycle. (This cutoff phenomenon is familiar to users of cathode followers; it appears in pulse and video circuitry as the storage effect which blocks current flow during negative-going pulses.) The charge in the capacitance must decay, between pulses of current, to a value which is less than the peak value of voltage developed on the next cycle of the carrier if trace distortion is avoided; the distortion causes a loss of high-frequency response. An *RC* integrator, shown in Fig. 29, is usually used after the detector to smooth out any remaining high-frequency variations. The critical frequency for the integrator circuit should be about 100,000 cps.

The main practical disadvantage of the infinite-impedance detector is the fact that

it cannot be used to develop a control signal voltage for AVC or AGC use. For this reason, a separate AGC rectifier is usually used. It is normally isolated by a separate amplifier to prevent the variable loading of the AGC detector from distorting the signal supplied to the signal detector.
FIG. 31. Regenerative detector.

43. The Regenerative Detector. The regenerative detector, a special form of the grid-leak detector, differs from its companion primarily in the presence of a feedback circuit which makes the detector an oscillator producing weak oscillations as well (Fig. 31). This feedback circuit, in developing weak oscillations, introduces a reference carrier for the incoming signal to be differenced or mixed with, and also supplies the losses of the tuned circuit, permitting it to appear to have an extremely high Q and, as a result, to build up the incoming signal by a factor which may be as high as a million times.

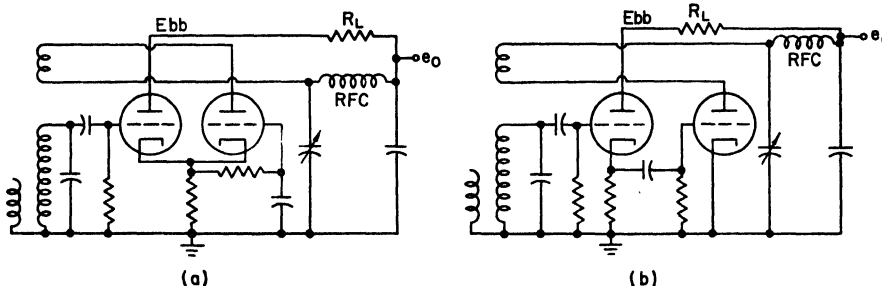
The oscillation-stabilizing circuit of this detector is adjusted to have a critical frequency which is in the low audio range so that the beat between the incoming carrier and the local oscillation may be observed. (The loading is obtained from


FIG. 32. Special regenerative detectors.

diode loading in the grid circuit.) Often this critical frequency may be as low as or lower than 500 cps, thereby making possible values of effective Q of the tuned circuit as high as 30,000 or more. The adjustment of the feedback to give oscillation without pulsing or *squegging* is very critical since the time constant of the grid-leak circuit is very long compared with the decay time of the tuned circuit ($2\pi Q/\omega$).

Two improved forms of regenerative detectors are shown in Fig. 32*a* and *b*. The operation of these detectors is identical with that of the more conventional type except in one respect—the diode loading is not coupled directly into the tuned circuit but is isolated from it by a low-gain amplifier or cathode follower. The setting of the regenerative coupling is somewhat more critical because of the absence of the variable diode loading on the tuned circuit; the control is accomplished by the variation of transconductance instead. The absence of the variable loading on the tuned circuit greatly enhances the stability of the detector and makes its use on a-m signals practical. Otherwise, the feedback or regeneration must be reduced to a setting which is just below oscillation with a-m signals.

44. Limiting and Clamping. Devices having nonlinear amplitude characteristics as a function of applied voltage may make excellent limiters and clamping circuits. Ideally, a clamping circuit normally cuts or clamps a signal at a certain voltage level and for one polarity, whereas a limiter clips on both polarities at predetermined voltage

levels. As with detectors, devices which possess piecewise-linear characteristics make the best limiting and clamping elements, particularly if one or two of the sections have zero gain for input signals within their control ranges, with the remaining linear area providing a constant gain.

The characteristics of a signal after passage through a clamping circuit are dependent on the amplitude of the applied signal unless the clamping circuit has ideal piecewise-linear characteristics with the break point between the linear sections occurring at the zero level of the input signal. Since ideal conditions are hard to achieve in practice, the applied voltage should be of sufficiently high amplitude that any anticipated variations will not introduce difficulties. (Consequently d-c restoration or clamping in TV circuits is usually accomplished at the picture-tube grid or cathode.) Figure 33 shows the result of clamping a sine wave.
FIG. 33. Circuit passing a half wave.

45. Limiting. Limiting is usually used to minimize the effect of noise energy on the operation of noise-sensitive circuits. In a sine-wave signal, the voltage actually remains in the neighborhood of the peak value much longer than it remains near zero, with the result that small variations due to noise may be suppressed by limiting the amplitude. The clamping minimizes the variation in the energy per half cycle in the signal, taking out both noise and amplitude modulation. As can be seen in Fig. 34, the only noise which can affect the received signal in a heavily limited signal is that which occurs during the transition periods.

FIG. 34. Effect of limiter on signal with noise.

The total energy per half cycle of a voltage wave may be found by integrating the square of the output voltage over the period of the wave. When the signal voltage is less than the limiting level, the value follows the integral of a sine-squared function, whereas, when the voltage is greater than the limiting level, the value is the integral of the limiting value. The total energy per cycle then is proportional to

$$P = (a^2 - b^2) \arcsin (b/a) + \pi b^2 - b \sqrt{a^2 - b^2} \qquad (37)$$

where the amplitude of the sine wave a is equal to or greater than the limiting level b. In case a is infinite, the first and third terms cancel, leaving $P = \pi b^2$; in case $a = b$, $P = \pi b^2/2$. Consequently, such a limiting circuit restricts the total energy in a limited wave to a 2:1 ratio, or a voltage ratio of $\sqrt{2}$:1. Additional limiters can be used to restrict the voltage variation even further.

For applications in which phase stability is important, limiting should be accomplished by the use of a circuit which is designed to clamp symmetrically on both polarities. Otherwise, the tuned circuits which are excited by the voltage and current pulses may introduce a phase shift as a result of the dissymmetry. For ordinary communications use a transient of little importance would be introduced; in precision instrumentation, however, the transient could be troublesome.

46. The Diode Clamp Circuit. The single diode, as in Fig. 35*a*, may be used as a clamping device or a rectifier. Its characteristics depend primarily on its mode of operation; if it is used to couple a source and a load both of which have either reactive

characteristics (of the same polarity) and negligible d-c resistance or resistive characteristics and negligible reactance, it will restrict the output at a selected value of voltage. Otherwise, the reactive element or elements can store energy and discharge it slowly, causing clamping to occur at a voltage level which is a function of input voltage.

The diode, as normally used, distorts the applied signal voltage, thereby generating harmonics of the applied signal. For a sine-wave voltage clamped at the zero voltage line, the harmonics generated have the relative amplitudes

$$A_n = 2/(n^2 - 1) \qquad (n \text{ even}) \tag{38}$$

Since the amplitudes of the harmonics are nearly inversely proportional to the square of the harmonic order, the harmonic generating efficiency of a clamp circuit designed
Fig. 35. Clamping and limiting circuits.

to clamp at the zero voltage point is very poor. Efficiency may be improved by shortening the conduction cycle, giving the relative amplitudes values in accordance with

$$A_n = K \left\{ \frac{C \sin [(n-1) \arccos (a/c)]}{n-1} + \frac{C \sin [(n+1) \arccos (a/c)]}{n+1} - \frac{2a \sin [n \arccos (a/c)]}{n} \right\} \tag{39}$$

where a is the bias voltage applied and c is the amplitude of the applied sine wave [the conduction angle is plus or minus arccos (a/c)]. When a is nearly equal to c, A_n is very similar to the corresponding coefficient for the Fourier spectrum of a rectangular pulse of approximately equal duration.

A pair of diodes may be connected in a balanced circuit as shown in Fig. 35*b* to provide either full-wave rectification or frequency doubling. A low-pass output circuit is used with a full-wave rectifier, and a circuit is tuned to the second harmonic when the circuit is used as a frequency doubler. The input voltage should be balanced with respect to ground with the circuit in Fig. 35*b*; otherwise either unsatisfactory smoothing or unsatisfactory doubling will result.

A circuit having two diodes connected as in Fig. 35*c* may be used as a limiter; the two diodes are both biased to be nonconducting for small values of signal voltage. The bias circuit shown in the figure (consisting of r_a, r_b, and r_c) should be adjusted to place the conduction voltage level of one diode as much positive with respect to the reference point a as the other conduction level is negative. Then the limiting achieved is symmetrical, and maximum operational stability for the limiter should result. The current flowing in the bleeder circuit should be large compared with the peak diode current expected (at least twice the peak value) to make certain that the limiting levels do not change with applied signal voltage. The dual-diode limiter has one major disadvantage—it has an amplification which is appreciably less than unity. Where higher amplification is required, the gated-beam limiter and the cathode-coupled limiter should be considered.

47. Triode and Pentode Clamp Circuits. Triode and pentode tubes are often used in clamping amplifiers by taking advantage of the clipping action which can be obtained

from the grid conduction in the positive-bias area. As shown in Fig. 36, a series resistance R_d may be introduced in series with the grid, or the internal resistance in the source itself may be used to limit the grid current and provide the clamping; the value of resistance selected should be large enough that the product of the input conductance of the grid (g_c or g_{11}) and R_d is large compared with unity and g_c or g_{11} is the input or base conductance for tubes or transistors, respectively.

FIG. 36. Triode clamp circuit.

The existence of clamping due to cutoff in triode and pentode tubes makes them useful in limiters as well as clamping circuits. Of the two tube types, the pentode usually is somewhat more effective because of the sharper cutoff obtainable. The range of screen voltages which may be used with pentodes makes available a gap between grid conduction and current cutoff which may be adjusted to suit the convenience of the user. The load impedance may be selected to take advantage of the characteristics of the individual tube. Triode and pentode clamping circuits may be designed to function at carrier frequency by the use of a tuned load impedance or at modulation frequency by the use of a load resistance alone.

In the use of either a triode or a pentode as a limiter, the bias selected for the control grid should be that which corresponds to a plate current half that for zero bias. Since the symmetry of operation is rather poor otherwise, the introduction of some cathode degeneration may improve the operating characteristics if the operating frequency is sufficiently low (usually less than 1 Mc). Degeneration increases the amount of grid-voltage change required to achieve limiting, with the result that an adjustment of either the input signal amplitude or, with a pentode tube, the screen voltage, or both, may be required to make the limiting effective. The peak-to-peak voltage at which limiting commences may be found from the equation[1]

$$E_t = I_{kp}R_k - E_{cn} \tag{40}$$

where E_t is the peak-to-peak voltage at which limiting commences, I_{kp} is the total cathode current at zero bias, E_{cn} is the approximate bias required to cut off the plate current in the tube, and R_k is the resistance between cathode and ground.

[1] Standard IRE definitions are small letters as symbols along with a single subscript for small-signal or instantaneous currents, voltages, and conductances or resistances. For fixed values at specific operating points, such as at the static operating point with or without signal, however, a capital-letter symbol is used along with two or more identifying subscripts. The following table indicates some additional definitions used in this chapter:

Instantaneous symbol	Static no-signal	Static with-signal	Grid-bias limit: Positive	Grid-bias limit: Negative
i_b	I_b	I_{bs}	I_{bp}	I_{bn}
e_c	E_c	E_{cs}	E_{cp}	E_{cn}
e_b	E_b	E_{bs}	E_{bp}	E_{bn}
g_m	G_m	G_{ms}	G_{mp}	G_{mn}
g_p	G_p	G_{ps}	G_{pp}	G_{pn}
g_{mi}	G_{mi}	G_{mis}	G_{mip}	G_{min}
K	K	K_s	K_p	K_n

The only symbol above which is somewhat irregular, K, is so because of the standard use of K for small-signal gain. Consequently, the required subscripts are added directly. As can be seen, the additional symbols for the parameters at the maximum positive grid bias and the most negative grid bias are made by substituting either a p or an n, respectively, for the s used to specify the static with-signal conditions. In this way, the characteristics at the bias limits may be specified, simplifying distortion and mixer-design calculations.
48. The Cathode-coupled Limiter. The cathode-coupled limiter (Fig. 37) makes use of a cathode follower and a grounded-grid amplifier connected in cascade; the first of these tubes acts as a repeater and at one limit shuts off the plate current in the output amplifier, and at the other limit has its own current shut off by the action of the amplifier. Because limiting is accomplished by the cutoff of the plate current in either the one or the other tube, rather good symmetry can be obtained if the bias is adjusted to place the static operating point of the amplifier at the mid-point of the output characteristic (Fig. 38). The cathode-coupled limiter has the advantage of having a small-signal amplification in the active range between 5 and 20. It is normally used at frequencies below 10 Mc, and the balanced diode limiter above 10 Mc.
FIG. 37. Cathode-coupled limiter.
FIG. 38. Input-output relation, cathode-coupled limiter.

49. The Gated-beam Limiter. The gated-beam limiter is unique in that the tube used has a transconductance which varies approximately symmetrically about the mid-point of its useful bias range, namely, between zero bias and collector cutoff bias. This phenomenon is shown by the curves in Fig. 39 for the 6BN6 tube. When this tube is used as a limiter, the quadrature grid is grounded, and the input bias is placed at the value required to produce maximum static transconductance. The limiting action occurs in the tube both with the quadrature grid grounded and also with either external or self- (negative capacitance coupled) excitation. The screen or accelerator voltage for this tube may be selected to give the width of conduction gap desired; the value chosen should be small enough that the power dissipation of the various electrodes is well within their ratings and at the same time large enough to give an adequate collector output signal.

50. Mixers. Electronic mixers are multipliers; they generate sum and difference frequencies by the multiplication, transforming the modulation carried on a received signal onto the frequencies generated by the multiplicative action. Mixing or multiplication of voltages is accomplished by causing one voltage to vary the amplification experienced by the other in passing through the multiplier. The equation controlling this action is

$$K = f(e_r) + e_s f'(e_r) \qquad \text{or} \qquad e_0 = \int f(e_r) + e_s f(e_r) \tag{41}$$

where e_r is the reference oscillator voltage, e_s is the signal voltage, with e_r much larger than e_s, and $f(e_r)$ expresses the variation of the voltage amplification of the multiplier as a function of the reference voltage. The amplification function $f(e_r)$ may be written in power-series form as

$$f(e_r) = K_0 + K_1 x + K_2 x^2 + K_3 x^3 + \cdots \tag{42}$$

where x represents the ratio of the instantaneous value of e_r to the peak value of e_r, e_{r1}, and the Ks are the coefficients of the expansion.

The conversion amplifications for some of the more commonly used conditions of operation are listed in Table 4.

When the input and the output frequencies are low enough that values of K_p greater than 2 or 3 may be obtained with a triode or a multigrid tube, then the mixing

resulting from a linear variation of amplification is usually chosen in preference to the mixing obtained from a diode under piecewise-linear operating conditions. Since diode and triode mixers have lower inherent noise levels than multigrid mixers, they require much less signal amplification ahead of the mixer; unless, however, the locally generated oscillator signal is adequately isolated to minimize detuning with diode and
FIG. 39. Characteristics, 6BN6.

triode mixers, poor stability may result. The multigrid mixer has been used extensively for low-frequency receivers because of the greatly reduced coupling between the input and local oscillator circuits.

In applications requiring the precise determination of carrier phase, even multigrid mixers may have sufficient coupling to give unstable operation. Stabilization may be obtained for such applications by the use of low-impedance input circuits (a broad-

band 50-ohm termination on both the input grids is ideal) and the use of by-pass capacitors on the screen and cathode which provide adequate by-pass action to a frequency which is at most a tenth of the mixer output frequency.

51. The Cathode-coupled Mixer. The cathode-coupled circuit shown in Fig. 40 can be used to provide mixing action with low noise and negligible interaction between the inputs. This circuit is of growing importance because of its inherent stability coupled with its low noise figure. The magnitude of its conversion amplification, since it is dependent on the linear term in the function $f(e_r)$, may be evaluated in terms of the coefficient K_1 of Eq. (42). As long as f can be represented in terms of a quadratic expression in (e_r), then $K_1 = (K_p - K_n)/2$ and the conversion amplification is
FIG. 40. Cathode-coupled mixer.

$$K_c = (K_p - K_n)/4 = K_1/2 \quad (43)$$

52. The Triode Mixer-design Technique. The simple triode mixer may be used at very high frequencies in applications in which the difference, or i-f, frequency is high. Under such conditions, the efficiency of the cathode-coupled mixer may be low. The triode mixer is commonly used in television and u-h-f communications receivers.

The calculation of the conversion amplification of a practical triode mixer requires the use of the small-signal data on the characteristics of the active device over the full range of operation. Because the mixer is designed to suppress the incoming signal frequencies and pass only the difference frequency, it has an output impedance approaching zero at the two input frequencies, and a finite output impedance (between 1,000 and 100,000 ohms) only at the difference frequency. For this reason, the input load lines R_{Li} in Fig. 41 are nearly vertical, and the family of output load lines R_{Lo} has a slope corresponding to the i-f output impedance. A set of output load lines is required because the local oscillator voltage in effect changes the operating point of the mixer amplifier instant by instant.

The basic amplification data may be calculated at a series of points which are at the intersections of the input load lines with respective typical output load lines for different values of local oscillator voltage. The output load lines selected from the family usually are chosen to represent equal increments of reference signal voltage between the negative and positive limit values. A value of transconductance and a value of plate conductance are read at each intersection, and the data at each intersection are inserted in the equation

$$K = -g_m R_L/(1 + g_p R_L) \quad (44)$$

where R_L is the tuned impedance at the output frequency. The conversion gain may then be determined from the appropriate equation in Table 4.

The local oscillator voltage should be large enough to shift the grid bias of the tube from approximately zero to the cutoff bias along the input load line. The exact value of the voltage is not critical as long as it is large enough to reduce the amplification obtained on the negative bias limit (E_{cn}) to a value which is less than a quarter of the value at the positive limit bias voltage (E_{cp}). The use of grid-leak rectification is recommended to provide the proper static bias and the correct operating conditions for the control grid of the triode mixer.

53. Multigrid-mixer Design. The design of the multigrid mixer circuit differs from that for the triode mixer primarily because of the use of separate grids for the introduction of the incoming signal voltage and the local oscillator voltage. The data required for circuit design, as with triodes, include static data on the variation of plate current with screen voltage at the various values of grid bias, and also data on transconductance as a function of the same parameters. These data may be organized to provide, first, the information required for the design of the mixer as an amplifier and, second, to permit a modification of the design to provide the required mixer characteristics. The first step, the design of an amplifier, may be accomplished by the use of the manufacturer's recommended operating conditions or by the use of conductance
FIG. 41. Plate characteristics, 12BZ7.

techniques.[1] The second step, calculation of the converter characteristics, is readily accomplished by a special set of conductance curves called screen-converter curves. These curves (Fig. 42*b* and *c*) include two sets, one showing the variation of plate current with screen voltage for constant values of bias on the first grid along with contours of constant transconductance for the third grid, and the second set showing the variation of plate current for constant values of bias on the third grid along with contours of constant transconductance for the first grid. The bias applied to the grid whose transconductance contours are shown is chosen to be approximately that for which the maximum transconductance is obtained.

The conversion amplification of the pentode mixer may be determined directly from the special curves if the output impedance of the mixer circuit (the impedance Z_L of the i-f transformer) is known. As with the triode mixer, the amplification as a function of the local oscillator voltage may be calculated in terms of the transcon-

[1] Pullen, K. A., Conductance Curves Speed Design of Pentode R-C Amplifiers, *Tele-Tech*, July, 1953.
FIG. 42a. Screen characteristics, 6CS6. P_P and P_{c2} = 1 watt.
FIG. 42b. Screen-converter curves, 6CS6, E_{c1} = 0.

ductance and converted into terms of K_0 and K_1 in Eq. (42) ($K = -g_m Z_L$). The conversion amplification may then be determined by the help of Table 4.

The curves for the 6CS6 tube in Fig. 42 show several interesting characteristics which are rather typical of conventional mixer tubes. For example, the maximum available transconductance for the first control grid is nearly twice that for the second,

indicating that more effective mixing may be obtained by placing the incoming signal on the first grid. An improvement of the over-all noise figure results since the noise generated is independent of the choice of input grid, whereas the relative output signal is dependent on the maximum transconductance. In addition, the screen current is abnormally high with multicontrol tubes; it may be as much as four times the plate current, reducing severely the available transconductance to the plate and making
FIG. 42c. Screen-converter curves, 6CS6, $E_{c3} = 0$.

the noise figure even poorer. Furthermore, under the usually recommended operating conditions, a failure of the local oscillator signal results in excessive power dissipation on both the screen and the plate of the tube.

The amplitude of the local oscillator voltage required by the second control grid is appreciably larger than that required by the first grid because of the differences in the transconductances. The peak-to-peak amplitude of the voltage required may be read directly from the converter curves since the local oscillator signal is required to shift the bias sufficiently to change the transconductance from the zero-bias value to a value near zero (at most a quarter of the maximum value). The conversion transconductance available then is approximately a quarter of the difference between the maximum and the minimum values. Usually the screen voltage E_{c2} selected should be sufficiently high to make available as much as possible of the transconductance developed by the tube without permitting damage to the tube with a failure of local oscillator voltage. The value of E_{c2} usually lies between 50 and 75 volts. The final circuit used is shown in Fig. 43.

FIG. 43. Multigrid-mixer circuit.

54. F-m Detectors. Phase and f-m detectors are required to produce an output voltage which is a function of either the applied phase or frequency rather than a

function of the applied signal amplitude. The amplitude of the signal applied to these detectors should be limited to provide constant excitation of the detector; otherwise the output signal is a function of both the frequency and the incoming amplitude of the signal being processed. The detector converts f.m. or p.m. to a.m. and then detects the resulting a.m.; when the amplitude and phase characteristics are linearly variable with frequency or phase, respectively, a.m. proportional to the original frequency or phase is obtained.

If a current of the form indicated in Eq. (45) is applied to a circuit having an amplitude response which varies linearly with frequency, a voltage of the form of Eq. (46) results:

$$i = I_0 \cos (\omega_c t + \theta + m \sin at) \tag{45}$$
$$e = Z_0 I_0 [1 + Sma \cos (at - Pa)] \cos [\omega_c t + m \sin (at - Pa)] \tag{46}$$

where S = slope of impedance characteristic $\Delta Z/\Delta\omega$
P = slope of phase characteristic $\Delta\phi/\Delta\omega$
Z_0 = impedance at carrier frequency
a = angular modulation frequency

Such an impedance is obtained approximately, over a limited frequency range, on the side of the resonance curve of a parallel-tuned circuit or near the resonant frequency of a series-tuned circuit. The resulting voltage is amplitude-modulated at the modulation frequency $a/2\pi$ to a degree Sma. The phase shift of the modulation envelope through an angle Pa and the remaining f.m. or p.m. are usually of no interest. The actual demodulation is made ordinarily in a conventional linear-amplitude detector.

For f-m waves the modulation index is inversely proportional to the modulating frequency $a/2\pi$ and directly proportional to the frequency deviation Δf, where Δf is defined by

$$\Delta f = ma/2\pi = \Delta\omega/2\pi \tag{47}$$

The depth of the amplitude modulation m_a obtained is given by

$$m_a = Sm_f a = S(\Delta\omega) \tag{48}$$

For p-m waves the modulation index (m_p) is independent of the modulating frequency. The output is then distorted unless the demodulated signal is passed subsequently through a circuit whose response is inversely proportional to the modulation frequency.

55. Balanced Frequency Detectors. A single frequency-amplitude converter of any simple type responds to spurious a.m. present in the original signal or introduced by the selective response of the i-f tuned circuits. The differentially combined outputs of two detectors, operated from converters with opposite slopes, produce a net output which is nearly linear with respect to desired frequency deviation but zero at the carrier frequency. This arrangement, when carefully tuned to the carrier, gives an output from spurious a.m. which is proportional only to the instantaneous deviation and is, therefore, masked to a great extent by the desired signal. The response to spurious a.m. may be reduced further by an amplitude limiter ahead of the detector stage, or by using a converter circuit which dynamically maintains the output level substantially constant, regardless of any changes in the input amplitude which are at an audible rate.

The most obvious balanced frequency detector or *discriminator* is a pair of circuits, one tuned slightly above and one slightly below the carrier frequency and provided with separate rectifiers whose outputs are combined differentially. A more satisfactory type is the phase-shift discriminator shown in its more common form in Fig.44*a* and in one of the many possible variations in Fig. 44*b*. It combines two converters of opposite slopes and is operated from a single i-f amplifier or limiter. The primary voltage plus half the secondary voltage is applied to one diode, and the primary voltage plus half the secondary voltage, with reversed polarity, to the other diode.

The shape of the output-frequency characteristic of a phase-shift discriminator is satisfactory when the secondary inductance is equal to or slightly greater than the primary inductance, when the effective Qs of the circuits are approximately equal,

and when these circuits are overcoupled by an amount that depends on the available Q and the required maximum deviation.

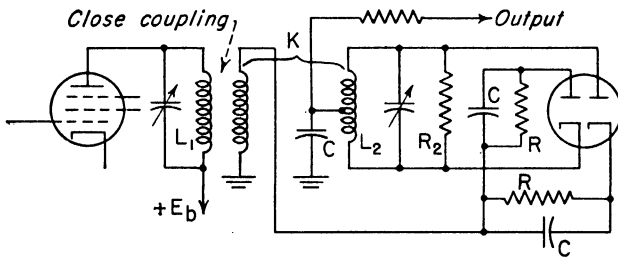
The primary, secondary, and output voltages of the phase-shift discriminator of Fig. 44*a* for an input current I at an angular frequency $2\pi(F + \Delta f)$ are approximately

$$E_1 = -2\pi FQLI \frac{1 + j2D}{4D^2 - 1 - K^2 - j4D} \tag{49}$$

$$E_2 = 2\pi FQLI \frac{jK}{4D^2 - 1 - K^2 - j4D} \tag{50}$$

$$\text{Output} = 2\pi FQLI\eta \frac{\sqrt{1 + (2D + 0.5K)^2} - \sqrt{1 + (2D - 0.5K)^2}}{\sqrt{(4D^2 - 1 - K^2)^2 + 16D^2}} \tag{51}$$

where $D = Q(\Delta f)/F$
$K = kQ = Q \times$ coefficient of inductive coupling
η = voltage rectification efficiency of diodes

The complex primary and secondary voltages, Eqs. (49) and (50), for $K = 3$ are shown in Fig. 45 for three values of Δf. The phase shifts of the primary and secondary
(a) Conventional


(b) Output balanced to ground

Fig. 44. Phase-shift discriminator.

voltages are in opposite directions as the frequency departs from the center frequency, tending to make the net output more nearly linear with frequency over a wide range.

Universal curves for normalized output, expressed by the radical fraction in Eq. (51), are plotted for $K = 1$, 2, 3, and 4 in Fig. 46. Only one-half of each curve is shown since the output curve for negative deviations is skew-symmetrical with that shown. Actual curves check closely with the calculated curves except when spurious couplings between leads or spurious capacitances to ground modify the results. (The output of the circuit of Fig. 44*b* has the same shape but only half the amplitude.) The value of K to be chosen, not to exceed 3.0, for maximum efficiency is such that $Q(\Delta f)/F$ for maximum deviation is as large as possible while still restricted to a linear portion of the curve. Deviation over too wide a range results in odd-harmonic distortion. Operation with the carrier considerably displaced from the frequency of zero response results in severe even-harmonic distortion.

Both diodes in parallel place a shunt load on the primary while they are in series with respect to the secondary. The resistor R_2 may be added to equalize the circuit Qs. As shown in Fig. 44*a*, the load resistors R are in parallel with the individual diodes, making the net effect of each diode and resistor approximately equal to $R/3$. The capacitors C are for r-f by-pass only.
FIG. 45. Voltages in phase-shift discriminator.

A phase-shift discriminator has an advantage over separate tuned circuits in that it may be made linear over greater deviations, since when properly designed the double peaking in the primary circuit and the opposite phase shifts in primary and secondary compensate for some rounding of the maximum response. The tuning is also simpler since the secondary circuit is adjusted to obtain zero response at the center frequency while the primary circuit is adjusted to obtain symmetry of response on either side of center.

FIG. 46. Relative response of phase-shift discriminator.

56. Ratio Detectors. A balanced discriminator very similar to that of Fig. 44*b* but provided with an electrolytic capacitor C_e across the two load resistors in series, as shown in Fig. 47, inherently maintains the output at a level substantially proportional to the frequency deviation and to the average i-f input regardless of a.m. Such a circuit is usually called a *ratio detector* since the ratio of the rectified voltages that appear across the two diodes is approximately equal to the ratio of the open-circuit a-c voltages developed between the two live terminals of the discriminator windings and ground. Many other series arrangements of elements produce equivalent results. Although these circuits are relatively new, they are already in wide use.

The electrolytic capacitor is equivalent to a battery having a voltage equal to the

average rectified voltage at any fixed operating level. Its voltage and the audio output voltage are substantially unaffected by rapid changes in input level, as with a.m., but follow the average input level, as with changes during tuning.

The same rectified current flows through both diodes and the load resistors since their d-c paths are in series. The rectified voltage *across* each diode is equal to its open-circuit peak a-c voltage minus the drop in the equivalent impedance of the source. The rectified current increases during outward a.m., though the division of diode voltages remains the same except for small changes in balance, owing, for example, to small differences between rectification efficiencies of the two diodes. The same is true for the balance for any downward a.m. which does not lower the instantaneous open-circuit peak a-c voltage below that across the electrolytic capacitor.
FIG. 47. Ratio detector.

The open-circuit voltages and impedances of the two sources change in the same ratio during frequency deviation, thereby providing differential output as in the conventional discriminator.

Effective nonresponse to a.m. in a ratio detector depends on a correlation of the load resistors with the diode efficiencies and with the impedance of the tuned circuits. This involves proper selections of the self and mutual inductances of the primary and secondary windings and of the r-f by-pass capacitance C. The rectification efficiencies cannot be more than about 50 per cent or the circuit will cut off on downward a.m. and introduce severe distortion. The primary inductance and resistors are usually smaller than in a conventional discriminator. No complete mathematical analysis is known to exist, and designs are checked by tests for linearity of desired output and for residual a.m. at various i-f and modulation levels.
FIG. 48. Dynamic and static characteristic of ratio detector.

Typical characteristics showing net output voltages with variations of input current for a fixed maximum deviation are shown in Fig. 48. The static characteristics are obtained with a slow change of input while the dynamic characteristics are obtained by superimposing a.m. The slope of the dynamic characteristic is proportional to the residual a.m. It may be negative at high input levels; *i.e.*, outward a.m. may cause the net output to decrease. The limiting *threshold*, or degree of downward a.m. to cause diode cutoff, and the ratio of the residual to the original a.m. for about 30 per cent original a.m. are illustrated in Fig. 49.

The residual a.m. is usually divided between balanced and unbalanced effects, as

shown in Fig. 50. In Fig. 50*a* the full line is the deviation characteristic without a.m. and the shaded area covers the limits of residual a.m. for about 50 per cent modulation at the input. The dashed lines show the limits of the envelope in the absence of amplitude reduction. The balanced and unbalanced components are shown (exaggerated) in Fig. 50*b* and *c*. The unbalanced effects may probably be accounted for by small changes in the effective diode input capacitances with level, and by harmonic voltage components introduced in the source impedances by harmonic components in the diode current.

The deemphasis time constant R_aC_a may be made 75 μsec in detectors for broadcast f.m. to compensate for the specified preemphasis.

57. The Gated-beam Detection Circuit. This circuit for the detection of f-m signals has come into common use. It has the interesting characteristics that the variation of the transconductance of the tube used as a function of bias is roughly symmetrical with respect to some value of bias, as is shown in Fig. 39. In addition to the limiting properties resulting from the transconductance symmetry, there exists a negative capacitance and a negative conductance coupling between the input grid and the "quadrature" grid, making possible the development of a quadrature voltage in the latter. The negative capacitance normally is much more effective in introducing coupling at i-f frequencies than is the negative conductance coupling. In the presence of the coupling a tuned circuit can be used to develop a voltage whose phase is a function of the frequency of the incoming signal, thereby producing discriminator action. Limiting is introduced through the action of the symmetrical transconductance characteristic of the first grid. In addition to the limiter curves, Fig. 39 includes a set of negative conductance contours for the quadrature grid. A typical circuit for a limiter-discriminator is shown in Fig. 52.

FIG. 49. Amplitude modulation in ratio-detector output.
FIG. 50. Residual a.m. in ratio-detector output.

58. Oscillating F-m Detectors. Several types of f-m detector have been developed which utilize the detuning action resulting from coupling of the incoming signal into an oscillator in phase quadrature. Of these, one of the better known is the Bradley detector.[1] It utilizes a multigrid tube having at least two control grids, the first used with the cathode to function as an oscillator, and the second for the input signal. The

[1] Bradley, W. E., Single Stage FM Detector, *Electronics*, **88**, October, 1946.

oscillator is adjusted so that it generates pulses of plate current (class C oscillation conditions). The amplitude of the plate-current pulses is controlled by the input signal, after which the pulses are re-formed to sine waves by a broadly tuned circuit and then coupled back into the oscillator. Such a coupled circuit (Fig. 53) reinserts its voltage into the oscillator itself in quadrature, changing the oscillator frequency and causing the average plate current to vary approximately linearly with frequency.

59. A Filter-type Discriminator. One of the limitations of the conventional discriminators is the rapid loss of output voltage at frequencies somewhat outside the normal operating range. This rapid dropoff, shown at *A-A* in Fig. 51, can cause spurious detection to take place, with the result that tuning of the receiver is made more difficult and also the weak-signal operation is deteriorated. The loss due to the
FIG. 51. Discriminator input-output relation.
FIG. 52. Gated-beam discriminator.
FIG. 53. Bradley f-m detector.

i.f., *B-B*, can be minimized by properly broad-banding the limiter amplifiers ahead of the discriminator. The disadvantage of a sharp loss of output outside the normal pass band may be avoided by the use of a pair of filters, one low-pass, the other high-pass (either *LC* or *RC* filters will serve), to supply the signal voltage to the rectifying diodes. These filters should be designed to have the mid-point of their cutoff range (critical frequency) located on the center frequency of the i-f channel. The voltage output as a function of frequency is shown in *C-C* in Fig. 51. As can be seen, the output voltage outside the detection range is approximately constant, making the discriminator insensitive to frequency excursions outside the detection region. The output characteristics are excellent for AFC use. A control system for AFC which is similar to that described has been reported by Mittelman.[1] A typical circuit is shown in Fig. 54.

60. Phase Detectors. Phase detectors can be used with f-m signals for the detection of modulation if the net phase shift developed in the detector is kept to less than 0.5 radian (otherwise nonlinear operation results). These detectors have recently received

[1] Mittelman, E., *Proceedings of National Electronics Conference*, 1946, p. 503.

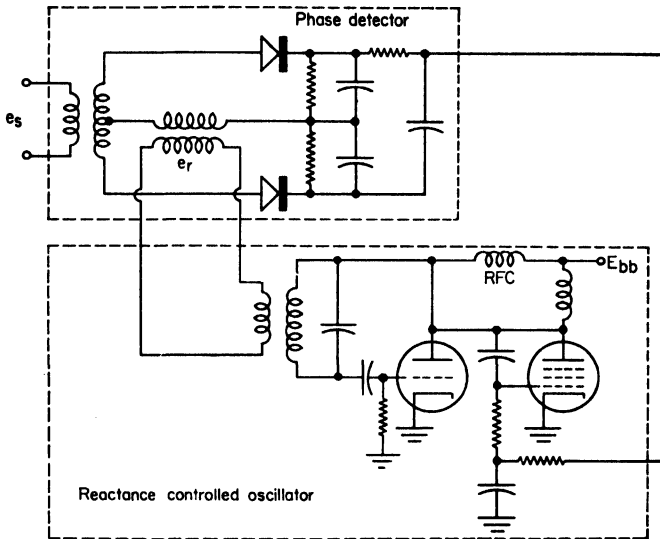
a great amount of attention because of the increasing importance of phase-measuring systems in instrumentation, and because of the detection properties obtained with them. Some of the basic properties of these detectors are described in more detail in Sec. 92. Phase detectors may be used to control reactance-modulated oscillators to provide detected signals relatively free of noise in the detected output; a typical circuit for one is shown in Fig. 55.
FIG. 54. An *RC* discriminator.


FIG. 55. Phase-lock circuit.

Phase detectors require a local source of signal as well as an external received signal, and they measure the relative phase between the two signals. The output voltage from the phase detector is a function of the cosine of the phase angle between the received voltage and the locally generated voltage, with the result that linear phase detection is available only for a narrow range of phase angles in the neighborhoods of 90 and 270 deg. (This is the reason that phase detectors are seldom used for ordinary f-m communication systems.) Phase detectors with their related control circuits can keep two frequencies in a fixed phase relation to within a few degrees, the exactness being dependent primarily on the phase transients and noise in the original and the reference signals.

Any circuit which may be used for a balanced modulator may also be used as a phase detector, provided only that the active elements are properly matched. Dual diodes are commonly used as active elements because of the relative ease of obtaining adequately matched pairs. A typical circuit using diodes is shown in the portion of Fig. 55 marked Phase Detector.

The phase detector can yield useful data only as long as the phase between the signal and the reference is almost exactly ±90 deg. Since phase detectors are used to lock the frequency of a variable-frequency oscillator to the frequency of a received signal, they must be followed by low-pass circuits in the output which have sufficiently fast response to correct both the phase and the frequency before the phase error actually reaches 90 deg. The band width required in the low-pass filter depends on both the frequency change and the phase sensitivity of the frequency-control circuit.

MODULATORS

Modulators are used to impress intelligence on a signal conveying information from one place to another. Among the commonly used forms are amplitude, phase, frequency, balanced, and pulse modulators. Modulators are very similar to mixers; in fact the principal difference is that, in the modulator, one of the two applied frequencies is the modulation and the other the carrier, whereas in a mixer one frequency is a modulated carrier and the other is a reference carrier.

Modulation may be accomplished on signals of either low or high amplitude. In the former the modulation normally is accomplished early in the process of development of the output signal and is amplified to provide the required final output energy. On high-amplitude signals, the modulation is accomplished in the final amplifier, normally through the use of some form of class C modulator. Each of these arrangements has certain advantages and disadvantages in practical systems; for this reason, each is discussed briefly before the different circuit arrangements available are investigated.

61. Low-level Modulators. Low-level modulators are commonly used in SSB, f-m, and pulse-code systems, but only occasionally for conventional a.m. Unless the amplitude characteristic conveys no information, as in f.m. and sometimes in pulse systems, linear amplifiers must be used with low-level modulators to minimize the amplitude distortion. When properly designed, a system using a low-level a-m modulator followed by linear amplifiers may yield a lower over-all distortion than a high-level system. The introduction of a-m modulation at high power level causes distortion as a result of the apparent reversal of sign of the source impedance of the modulator when the modulation signal voltage is negative (Fig. 56). The resulting distortion can be shown theoretically to be the result of the fact that both the peak and the valley amplitudes of the modulated wave have been reduced without any corresponding reduction of the amplitude of the unmodulated carrier signal.[1] The final amplifier draws power from the modulator when the envelope amplitude is maximum but returns power to the modulator when it is minimum.

FIG. 56. Effect of modulator impedance on amplitude modulator.

62. High-level Modulators. High-level modulators are used almost exclusively in the production of a-m signals and pulse (amplitude) modulated signals. They consist of active devices used in class C amplifiers (control electrode biased statically to cut off all current flow with the carrier removed), the circuit being arranged so that the modulation controls the total carrier energy which can be developed. In the usual

[1] Reinartz, John L., "Increased Audio without Splatter," Eimac Publication.

form, plate modulation, the plate-supply voltage (with triodes) or the plate- and screen supply voltages (with tetrodes and pentodes) are varied by the modulator, causing a variable amount of tuned energy to be available in the plate circuit, producing amplitude modulation of the applied carrier voltage. The system is efficient but is only relatively free of distortion unless extensive feedback networks and artificial loading networks are used to compensate for the nonuniform loading on the modulator.

AMPLITUDE MODULATORS

63. Absorption Modulators. Absorption modulation is obtained by varying a resistance either in series with or in parallel with the load in accordance with some function of the modulating voltage. In Fig. 57*a* suppose that R_v is a resistance which includes the load and which is varied linearly with the modulation or

$$R_v = R_0(1 + M) \tag{52}$$

where M = instantaneous value of the modulation.

The output voltage e_2 is

$$e_2 = \frac{e_1 R_v}{R + R_v} \tag{53}$$

where e_1 = applied voltage
R = resistance of the source

The ratio of e_2/e_1 is plotted against R_v/R in Fig. 58, which indicates that reasonably linear operation is obtained over a small portion of the curve when R_v is small compared to R. The dashed curve is the output voltage across R as a load when R_v is used as a variable series resistor. Physical resistances can be varied over a limited range, say three to one. The usable portion of the curve of Fig. 58 is then limited to the section marked *ab*. The efficiency and the effective degree of linear modulation of the output are low in any case.

Fig. 57. Method of absorption modulation.

The plate resistance of a tube as controlled by the modulating voltage applied to its grid may be used as the variable resistor for absorption modulation in parallel with the output load as shown in Fig. 57*b*. Since the plate resistance is not a linear function of the grid voltage, the over-all linearity may then be improved somewhat by working on a portion of the tube characteristic which tends to cancel the required curvature indicated in Fig. 58. Tests are then made for linearity of load voltage vs. grid voltage.

Fig. 58. Linearity in absorption modulation.

The plate conductance required of the tube is proportional to the resistance R_v when a quarter-wave transmission line or its filter equivalent is interposed between the tube and the load. The required plate conductance g_p is then

$$g_p = \frac{R_v}{Z_0^2} \tag{54}$$

where Z_0 = image impedance of the line.

Absorption modulation has been used to supplement other modulating methods over portions of the modulating cycle.

64. Grid Modulators. Grid modulators operate with carrier and signal voltages applied to the same or separate grids as illustrated in Fig. 59*a* or *b*. The plate current
FIG. 59. Types of grid modulators.

may be calculated by Eq. (31) for low levels when the plate current is not swung to cutoff. The action is illustrated in Fig. 60 for the connections of Fig. 59*a* and for a square-law tube. Curve *a* shows the input signal and carrier voltages superimposed, curve *b* the instantaneous plate current, and curve *c* the modulated output voltage with the l-f components filtered out.
FIG. 60. Low-level grid modulation.

In this case, when the applied voltage about the operating point E_v' is

$$e = E \cos \omega t + S_1 \cos a_1 t + S_2 \cos a_2 t + \cdots \quad (55)$$

where S_1 and S_2 are the signal amplitudes at frequencies $a_1/2\pi$ and $a_2/2\pi$, etc., the useful output current is

$$i = E(A_1 + 2A_2 S_1 \cos a_1 t + 2A_2 S_2 \cos a_2 t + \cdots) \cos \omega t \quad (56)$$

This may be written

$$i = E(A_1 + 2A_2 M) \cos \omega t \quad (57)$$

where M indicates the instantaneous applied modulating signal. The product $M \cos \omega t$, when expanded, produces all the pairs of side frequencies required for the modulated wave. There are no spurious modulation components. However, this mode of operation does not realize fully the power capability of the tube, and the modulation cannot approach unity.

A grid modulator is operated as a class C carrier-frequency amplifier for higher plate efficiency. A tube with a linear grid-plate characteristic is suitable. The bias is adjusted to about twice the value required for plate-current cutoff, and the carrier input voltage is adjusted until the peaks reach halfway between saturation and plate-current cutoff. The superimposed modulating voltage at signal frequency causes the positive peaks to vary widely in value as shown by curve *a* in Fig. 61. Curve *b* shows the instantaneous plate current and curve *c* the useful modulated output voltage with the l-f and carrier-harmonic components filtered out.

Linearity may be tested by observing the output at the test frequency for a range of bias voltages. The exact bias setting is then at the center of the linear portion of the test curve.

Grid modulators have the advantage of requiring small signal input power, particularly when the tubes are not driven to grid current, but have limited ranges of linear modulation and plate efficiencies of only 20 to 30 per cent. They are used ordinarily at low power levels.

Grid modulators are used for television signals since it is difficult to obtain reasonable operation with high-level plate modulation over the required wide band of television modulation frequencies. Triodes may be used in grid modulators if neutralized to prevent h-f feedback. The voltage, current, and power in the plate circuit have the following approximate relations for sine-wave modulation:

$$
\begin{aligned}
E_{\max} &= E_c(1 + M) \\
W_{\max} &= W_c(1 + M)^2 \\
i_{p\max} &= I_c(1 + M) \\
W_{av} &= W_c\left(1 + \frac{m^2}{2}\right)
\end{aligned} \tag{58}
$$

where the subscript c indicates the conditions for the carrier alone.

Fig. 61. Class C grid modulation.

An extra tube which is made to operate by adjustment of its grid and plate potentials over a portion of the modulation cycle to supplement the first modulator tube is sometimes used to obtain higher efficiency and at the same time preserve or even improve linearity of modulation.[1]

65. Plate Modulators. The constant-current plate modulator utilizes an a-f choke coil in the circuit which supplies plate power to r-f and a-f amplifier tubes, as shown in Fig. 62. The total plate current remains constant by virtue of the inductance of the choke. The instantaneous audio plate voltage is added to the plate supply voltage and over the audio cycle changes the latter to $E_b(1 + M)$. The r-f inductance L prevents the loss of h-f power in the audio tube, and C prevents the short circuit of the audio plate voltage.

The a-f tube, frequently called the *modulator*, supplies modulating power, but the actual modulation occurs in the plate circuit of the r-f tube.

The plate current of the a-f tube cannot be reduced to zero during the modulation cycle without introducing audio distortion. It is necessary, therefore, to operate the

[1] Terman, F. E., and J. R. Woodyard, A High-efficiency Grid-modulated Amplifier, *Proc. IRE*, **26**, 929–945, August, 1938.

audio tube with a higher zero-signal plate current than the radio tube to reach unity modulation without audio distortion. This is done by applying a higher plate voltage to the audio tube, either by using a by-passed resistance in the plate circuit of the r-f tube or by supplying the audio tube (or tubes) through transformer coupling as illustrated in Fig. 63. A further improvement is indicated in Fig. 63, since saturation of the transformer core is prevented by eliminating the d-c magnetizing component and since even-order audio harmonics are canceled by the push-pull arrangement. The efficiency of the system is increased by operating the audio tubes in push-pull class B. In transformer coupling the total d.c. is no longer constant but varies with the modulation.

Fig. 62. Circuit for plate modulation.
Fig. 63. Transformer-coupled plate modulator.

The voltage, current, and power in the plate circuit have the following relations for sine-wave modulation:

Tube and circuit voltage,

$$E_{\max} = (1 + m)E_b$$

R-f input power,

$$W_{\max} = (1 + m)^2 E_b I_b$$

Average r-f input power,

$$W_{av} = \left(1 + \frac{m^2}{2}\right) E_b I_b$$

Average output power,

$$W_0 = \eta \left(1 + \frac{m^2}{2}\right) E_b I_b$$

Average audio input power,

$$W_a = \frac{m^2}{2} E_b I_b$$

R-f plate loss,

$$W_p = (1 - \eta)\left(1 + \frac{m^2}{2}\right) E_b I_b \tag{59}$$

where E_b and I_b = d-c supply voltage and current
m = degree of modulation
η = plate efficiency of radio tube

The plate efficiency is high (often 0.7 to 0.8), and the chief disadvantage of plate modulation is the large amount of audio power which must be supplied.

The radio tube is operated as a class C amplifier with bias at approximately two times cutoff. Since the plate losses are 50 per cent higher with full modulation than for unmodulated output, the tube must be used at two-thirds its rated power. Low-mu triodes are suitable and ensure low plate and grid voltages.

Grid-leak bias helps in obtaining linearity up to complete modulation. Linearity may be checked by direct adjustment or by test at 60 cycles with a proper plate load for a range of plate voltage from 0 to $2E_b$.

66. Modulated Oscillator. Plate modulation was originally applied directly to the oscillator tube and circuit. Practically full modulation may be obtained with excellent linearity, but the arrangement has the disadvantage of introducing f.m. The frequency of the oscillator varies with the plate voltage, and, since in plate modulation this varies between $2E_b$ and 0 during full modulation, the oscillator frequency deviates from its mean value with the modulating signal.

The same circuits are used between the two tubes, and the same voltage, current, and power relations hold as with a plate-modulated amplifier. Linearity is obtained by adjusting the value of the grid leak.

Modulated oscillators are now considered suitable only for test equipment in which the f.m. is not objectionable.

67. Semiconductor Modulators. Copper-oxide and other forms of semiconductor rectifiers are applicable in bridge modulators and are used widely in carrier-current telephony. They function as carrier-operated switches for opening, shorting, or reversing the elements carrying the modulating currents. For such purposes they are the familiar dry rectifiers for 60-cycle power in miniature. Each unit consists of a small copper disk, one side of which is oxidized and placed in contact with a soft metal. Electrons flow most easily from the copper to the soft metal. The resistance of a $\frac{3}{16}$-in. unit at low frequencies is of the order of 100 ohms in the forward direction and from 10^4 to 10^5 ohms in the reverse direction. The current-carrying capacity is roughly proportional to the area of the disk, which may be $\frac{1}{16}$ in. or more in diameter. The voltage rating is increased by placing several disks in series. Bridge units are usually hermetically sealed with only the terminals brought out.

Copper-oxide rectifiers are not suitable for use at frequencies much above 1 Mc, except at low impedance levels on account of inherently large shunt capacitance. They are compact in size and eliminate the heater connections necessary in similar circuits using vacuum tubes. They maintain a satisfactory balance in carrier-suppression circuits using balanced modulators.

The power-series current equation for a copper-oxide unit converges slowly, and its characteristics are expressed more easily quantitatively in terms of resistance for different applied voltages. For voltages in the reverse direction and for less than 0.02 volt in the forward direction, the resistance is high and substantially constant. For forward voltages between 0.02 and 0.6 volt, the resistance is approximately

$$r = r_0 \epsilon^{-ke} \tag{60}$$

where k is a constant which may be as great as 18. For forward voltages larger than 0.6 volt, the resistance is low and nearly constant.

Representative circuits using copper-oxide units are shown in Figs. 64 and 65. In these figures, f_c and f_s indicate voltage sources at the carrier and signal frequencies, respectively. The impedances of the carrier source, signal source, and load are Z_c, Z_s, and Z_L, respectively. The forward-conducting direction of the units is shown by the arrows.

FIG. 64. Bridge modulator using nontube rectifiers.

Since the carrier and signal voltages are applied to conjugate terminals of the rectifier bridges, the resistance effects are balanced. In Fig. 64 the output signal is short-circuited for one polarity of the carrier cycle. In Fig. 65, the effective connections between the signal source and the load are reversed as the polarity of the carrier changes. This arrangement is called a *double-balanced* or *ring modulator*.

The frequencies of the current components produced in the individual rectifier units are determined qualitatively by an expansion of each of the terms of a power-series equation for the current. Current components of frequencies equal to the sums and

differences of the integral multiples of the carrier and signal frequencies appear in each unit in the forward direction. These combine additively or differentially in the connected circuits depending on the polarity. In flowing through the circuit impedance these current components produce voltages of the same frequency which are reimpressed upon the rectifier units. The final result may be obtained quantitatively only by a series of approximations. The frequencies of the components appearing in the circuit impedances are indicated in Figs. 64 and 65, where n is any whole number or zero, n_o is any odd number, and n_e is any even number or zero.
Fig. 65. Double-balanced or ring modulator.

The output impedances are designed as filters to eliminate voltages at frequencies involving undesired multiples of f_c. The useful output is at a frequency $f_c \pm f_s$, and, when double modulation is used, the carrier frequency f_c is eliminated.

By making the carrier voltage large in comparison with the signal voltage, the terms involving multiples of f_s may be reduced satisfactorily in magnitude. The units are operated with about 0.5 volt carrier across each disk in the forward direction. The optimum impedance in the signal and output circuits is

$$Z = \sqrt{R_f R_r} \tag{61}$$

where R_f and R_r are the resistances in the forward and reverse directions, respectively. The loss in conversion is then only 6 to 8 db.

Copper-oxide bridge modulators differ from van der Bijl vacuum-tube balanced modulators in that they transmit in either direction. They function equally well as modulators or demodulators.

The same circuits may be used for solid-state crystal diodes as for copper-oxide rectifiers. They have low self-capacitance, and single units are operable to frequencies of several hundred megacycles.

68. Balanced Modulators. When carrier voltage is applied in phase and modulating voltage is applied in push-pull to the grids of two modulator tubes, the carrier is balanced out in a push-pull output load. The circuit shown in Fig. 66 with two neutralized triodes is typical.

Fig. 66. Balanced-modulator circuit.

For exact balance of tubes and transformers, and over the range of signals for which the modulation characteristic is linear, the useful modulated output current from the two plates is

$$i_1 = E_c(K_0 + K_1 e_m) \cos \omega t \tag{62}$$

and

$$i_2 = E_c(K_0 - K_1 e_m) \cos \omega t \tag{63}$$

where E_c = maximum carrier voltage
e_m = instantaneous modulating voltage

The effective input current to the tank circuit is

$$i = 2K_1 E_c e_m \cos \omega t \tag{64}$$
which contains only the side bands. For a single modulating frequency $a/2\pi$, this reduces to

$$i = K_1 E_c e_m [\cos (\omega + a)t + \cos (\omega - a)t] \tag{65}$$

The voltage developed in the output circuit is

$$e = K_1 E_c e_m Z [\cos (\omega + a)t + \cos (\omega - a)t] \tag{66}$$

where Z = load transfer impedance.

This arrangement is used in suppressed-carrier transmission systems. It has the advantage of balancing out any even-harmonic distortion due to departure of the modulation characteristic from linearity, not considered in the above equations.

When the modulating input voltages to the two grids, the tube coefficients, and the effective load transfer impedances for the two tubes are unequal, the net tank circuit voltage is

$$e = E_c[K_0'Z' - K_0''Z'' + (K_1'e_m'Z' + K_1''e_m''Z'') \cos at] \cos \omega t \tag{67}$$

where the $'$ and $''$ values are for the first and second tubes, respectively. Some of the carrier remains when the balance is not perfect.

69. Applications of Balanced Modulators. Any combination of active devices may be used in a balanced modulator if the circuit is so arranged that it is symmetrical with respect to one of the input signals, causes one signal to be balanced out statically in the output circuit, and has sufficient nonlinearity so that neither signal is balanced out in the presence of a signal in the symmetrical input. This balancing out of the static carrier results in the development, in the modulation, of a complete set of modulation side bands but no carrier.

The carrier component can be reinserted in the output obtained from the balanced modulator; if it is introduced in phase with the original carrier signal, then either conventional a.m., controlled-carrier a.m., augmented-carrier a.m., or any of the related forms of a.m. may be obtained. If the carrier is reinserted in quadrature, however, phase modulation is generated; the phase deviation permitted is less than ½ radian if linear modulation is required. If the carrier is not reinserted, and one of the side bands is suppressed, then a single-side-band suppressed carrier (SSSC) is obtained.

The suppression of one side band may be obtained through the use of filters or through the use of balancing circuits. The so-called phase system of developing SSSC signals uses the phasing or balancing-circuit technique to eliminate one side band; it uses two balanced modulators along with two carrier voltages which are in phase quadrature along with modulation signals which also are in phase quadrature. Combining the output of the two modulators gives the desired SSSC signal.

A filter or rejection circuit also may be used to eliminate one of the side bands. For SSSC service, crystal filters are usually used, and for straight suppressed side band (but not necessarily suppressed carrier, as in TV) a constant-impedance band-rejection filter may be used. Crystal-lattice filters are used extensively for the rejection.

PHASE MODULATORS

Phase modulators are devices which apply modulation to a carrier signal by advancing and retarding the phase of the carrier voltage in step with the modulation information. Three common methods for the generation of p-m waves are (1) use of the balanced modulator with the carrier reinserted in quadrature, (2) the phasitron, and (3) the use of the *Serrasoid modulator* (Sec. 72).

70. Balanced Modulator Method of P.M. When carrier voltage is added into the output of a balanced modulator in such a way that the carrier phase lags or leads by 90 deg the phase of the phasor sum of the modulation side bands, then the side bands in effect retard or advance the phase of the carrier, giving p.m. and a small amount of a.m. (Fig. 67). The amount of modulation which can be introduced

linearly with such a modulator is limited to less than 25 deg, the maximum angle at which the sine can be approximated by the radian value of the angle. The resultant phase-modulated voltage e_p varies in phase from the new carrier E_c' by the angle

$$\phi = \tan^{-1} \frac{E_s \cos at}{E_c'} \tag{68}$$

which, for angles less than about 25 deg, is approximately
$$\phi \cong \frac{E_s \cos at}{E_c'} = m_p \cos at \tag{69}$$

FIG. 67. Vector relations in p.m.

The resultant voltage varies only slightly in magnitude and is

$$e_p = E_c' \cos (\omega_c t + m_p \cos at) \tag{70}$$

When modulating signals at more than one frequency are present, the coefficients m_1, m_2, etc., are proportional to the original a.m., and p-m waves are produced.

The small phase departure of less than 25 deg may be increased by frequency multiplication of the instantaneous frequency. The new voltage is then

$$e_p' = E_c' \cos (n\omega_c t + mn \cos at) \tag{71}$$

71. Phasitron. A tube, called the *phasitron*, gives a large amount of phase modulation proportional to the current in a coaxial modulating coil surrounding it.[1] The tube utilizes a radial electron stream formed into a disk with a wavelike edge. The scalloped beam is made to progress at a constant average angular velocity about the cathode by deflecting electrodes excited by a crystal oscillator, and alternately to strike anode areas connected to the opposite terminals of a balanced output circuit. The phase of the scalloped edge is advanced or retarded by the modulating field.

When modulating voltages of constant amplitude are applied to the coil, the current is inversely proportional to their frequency and f.m. is obtained directly. The phase shift over which the modulation is linear may be more than 360 deg so that less frequency multiplication is required to obtain the standard system deviation for f-m broadcasting than with conventional phase modulators.

72. The Serrasoid Modulator. The serrasoid modulator uses a crystal-controlled saw-tooth generator in conjunction with a low-frequency modulation voltage to produce a variable triggering time for exciting a blocking oscillator (Fig. 68). When the rising portion of the saw tooth crosses the control-voltage level, the blocking oscillator produces a pulse which can be filtered to provide a p-m carrier at a small multiple of the crystal oscillator frequency.
FIG. 68. Serrasoid modulator.

The excitation pulses are shown at e_i; they are filtered by a tuned circuit to reduce them

[1] Adler, R., A New System of Frequency Modulation, *Proc. IRE*, January, 1947, p. 25.

to a variable-phase sine wave. The resultant signal may then be multiplied as required.[1]

FREQUENCY MODULATORS

Frequency-modulation circuits are closely related to phase-modulation circuits since frequency is actually the rate of change of phase. If, therefore, a modulation signal is first integrated and then phase-modulated, the signal produced is identical with that obtained by direct frequency modulation. As a result, phase modulators are usually used to produce f.m. because of the better frequency stability which can be obtained with them.

Frequency-modulated waves are obtained by the method described in Sec. 70 when the modulating signal is passed through a filter whose response is inversely proportional to the signal frequency. The instantaneous frequency is multiplied several hundred times before the output is applied to the antenna.

73. Reactance-tube Modulator. Frequency modulation may be obtained, however, by the use of an oscillator coupled to a reactance tube, which introduces a fictitious capacitance, dependent on the modulation, into the oscillator circuit. This capacitance is made variable by having the modulation voltage vary the transconductance of the reactance tube, thereby causing the introduction of a variable magnitude of quadrature current into the oscillator (Fig. 69). The quadrature current appears to change the reactance of the tuned circuit of the oscillator, varying the frequency in step with the modulation voltage. The linearity of the resulting modulation is critically dependent on the characteristics of both the circuits and the reactance tube itself.

FIG. 69. Reactance-tube f-m modulator.

Either an integrator or a differentiator circuit may be used to couple the oscillator signal into the grid of the reactance tube; then the quadrature current from the reactance tube is reinserted into the tuned circuit of the oscillator to vary either the inductance or the capacitance. An integrator followed by an amplifier generates a capacitive current, and a differentiator circuit produces an inductive current. The magnitude of the quadrature current is controlled by the magnitude of the modulation voltage and by the transconductance of the reactance tube for each value of the modulation voltage.

A typical circuit is shown in Fig. 69 as one of many possible arrangements. Radio-frequency voltage, shifted in phase 90 deg from that appearing across the tank circuit, by means of resistance R in series with capacitance C, is applied to grid 1 of the control tube. The plate current of the control tube is substantially 90 deg out of phase with the tank voltage and provides an effective reactance which is controlled in magnitude by the modulating voltage on grid 3.

The change in oscillator frequency is proportional to the instantaneous modulating voltage when the control tube operates on a linear part of its characteristic and when the total change in effective reactance is small compared to the net average reactance.

Any component of control-tube plate current not at 90 deg with the tank voltage will introduce a.m. This is eliminated by adjusting the phase shift to grid 1 of the control tube.

The curve of frequency deviation from the carrier frequency should be linear with respect to the amplitude of the modulating voltage. It may be checked by applying direct voltages, over the operating range, to the modulating grid and observing the oscillator frequency.

The circuit illustrated in Fig. 69 provides f-m waves when the modulating voltages
[1] Day, J. R., Serrasoid FM Modulator, *Electronics*, October, 1948, p. 72.

are proportional to the amplitude of the signal. If the signal is passed through a filter whose output is proportional to the signal frequency before application to the control tube, p-m waves are produced.

PULSE SHAPING AND FORMING

Pulse shaping and forming may be accomplished either by the use of clamp or limiter circuits in connection with differentiator or integrator circuits, or through the use of regenerative pulse-forming circuits. The former are used when the duration of the shaped pulses is relatively unimportant, and the latter when the duration is important.

The shaping and forming of pulses with nonregenerative circuits requires combinations of amplification, clamping, and differentiation. The incoming wave should have characteristics resembling a pulse or a square wave if the stability of initiation is important. For the time jitter to be small, the initiating signal must switch rapidly across the gap between the lower and upper clamp levels. Consequently, rapid switching and clean clamping or limiting are required in conjunction with broadband amplification and differentiation circuits to form sharp stable pulses.

74. Active Pulse-forming Circuits. Active or regenerative pulse-forming circuits are used to generate pulses for devices like radar sets or digital computers; they are usually triggered by the signal from a nonregenerative pulse-forming circuit. Among some of the more common regenerative pulse-forming methods are:

1. One-shot multivibrator
2. Reflection on delay lines
3. Blocking oscillators
4. Delay lines in negative-feedback circuits
5. Combinations of circuits

Multivibrators and nonregenerative circuits can produce pulses having durations greater than 2 μsec, whereas the remaining circuits in the above list normally are used to generate pulses having durations between about 0.1 and 100 μsec.

75. The Single-shot Multivibrator. Normally the single-shot MV is used to convert trigger pulses into pulses having controlled amplitude, duration, and wave shape. The initiation pulse required to initiate any form of regenerative switch, and particularly multivibrators, must have both a greater amplitude and a longer duration than expected since the pulse duration must be sufficient to increase, dynamically, the loop gain of the regenerative device to a value greater than unity. The effects of capacitive loading make a sizable reduction in the apparent trigger amplitude, often with the result that the initiation pulse gets the device only partially triggered; switching, if it occurs at all, occurs only after a considerable delay. Delay times of between 10 and 30 μsec are by no means unusual.
FIG. 70. Cathode-coupled one-shot MV.

One of several possible types of one-shot MV is the cathode-coupled circuit shown in Fig. 70 together with typical output wave forms.[1] It may be adjusted for pulses of 2 to 2,000 μsec duration by changing the capacitance C and/or the various resistors. Positive or negative pulses are available at the plates of V_2 and V_1, respectively. A negative trigger may be used at the grid of V_2 instead of the positive trigger shown at the grid of V_1. In any case the dura-

[1] M.I.T. Staff, "Principles of Radar," Chap. 2, Secs. 13 to 16, McGraw-Hill, 1946.

tion of the trigger should be less than the desired pulse, and no other extraneous pulses should be coupled to either grid.

V_2 conducts between pulses since its grid-cathode voltage is approximately zero, while V_1 is cut off with a sufficiently high cathode voltage. A negative trigger at the grid of V_2 reduces the current and the cathode voltage to a point where V_1 starts to draw current. Almost instantly the negative voltage developed in the plate load of V_1 drives V_2 to cutoff. The current in V_1 is then temporarily stable as determined by the tube characteristic, resistors R_{L1} and R_k, and the terminal voltages. The negative peak voltage at the grid of V_2 is substantially equal to the drop across R_{L1} although it is modified slightly by the interelectrode and circuit capacitances. This grid voltage rises exponentially toward E_{bb} until V_2 again draws current. A positive voltage is regeneratively coupled almost instantly to the grid of V_2 via increased cathode voltage and reduced drop across R_{L1} so that V_2 momentarily draws more than normal current while V_1 is cut off. Grid current in V_2 then quickly reduces the grid voltage to normal, and the original conditions are restored.

The duration of the pulse depends on, but is less than, the time constant of C in series with R_{g2} and the combination of R_{L1} and the plate resistance of V_1. The pulse may be lengthened by returning the grid resistor R_{g2} to cathode rather than to E_{bb} since the voltage across the charging circuit for C during the pulse is then reduced. The duration of the pulse may be controlled to a limited extent by changing the size of R_{L1} since it determines the peak voltage to which C is charged during the pulse. Likewise this peak may be controlled by adjusting the tap of the voltage divider for the bias voltage applied to the grid of V_1. The pulse may be lengthened by increasing C, R_{L1}, or R_{g2}, or by reducing the voltage at the grid of V_1.

76. Pulse-forming Networks. Low-loss lines with distributed constants, open or shorted at the far end, or their network approximations, are used at various voltage levels for forming rectangular pulses of duration equal to the round-trip delay therein.

Figure 71*a* shows an open-end line with several sections of L and C approximating a uniform line. Figure 71*b* is a network simulating the sectionalized line more suited for operation at high voltage since, when completely charged, all the energy is stored in the single capacitance C_{st}, which is equal to the sum of the Cs in Fig. 71*a*. The circuits L_1C_1 and L_2C_2 have natural frequencies equal to $1/t_w$ and $2/t_w$, respectively. C_{st} is also equal to $t_w/2R_c$, where R_c is the characteristic impedance of the line. A pulse of half the initial voltage on the charged line appears across the load during the time the wave front travels to the open end and returns, when the line is discharged through a resistance equal to the characteristic impedance R_c. The traveling voltage pulse is negative and is reflected from the open end of the line with the *same* polarity to cancel the remaining voltage at the load. The discharge is by smaller proportional steps when the load resistance is greater than R_c, by decreasing alternately reversed steps when smaller.

(c) Circuit

(d) Pulse

FIG. 71. Discharge of open-end delay network.

Figure 72 shows a circuit in which a thyratron V_2 is made to act like a low-resistance electronic switch to discharge an open-end line by a positive trigger pulse on its grid. The network is desirably discharged through a load matched to the characteristic impedance. The by-pass diode V_3 provides current during any overshoot of voltage due to load mis-

match so that the plate of V_2 cannot become negative. The network recharges relatively slowly from the source E_{bb} through the charging diode V_1 and the inductance L after the pulse. This must be after the thyratron has deionized so that it will not short-circuit the source. The voltage on the line increases as the half cycle of an oscillatory charge to almost $2E_{bb}$, where it remains owing to the switching action of the diode V_1 until again triggered.
FIG. 72. Resonant charging of pulse-forming delay network.

The charging diode and the inductance may be replaced by a high resistance at the expense of charging the line to only the voltage E_{bb}. A rotary-gap switch is sometimes used instead of the thyratron; also the charging may be from an a-c source.

Figure 73*a* shows a shorted-end line with sectionalized L and C. In this case t_w is $2L_{st}/R_c$. Figure 73*b* is a network which simulates the uniform line on short circuit. When the line is connected to a source of constant current by opening a switch as in Fig. 73*c*, a pulse of voltage equal to $R_cI/2$ appears until the initial wave travels to the end of the line and returns with *reversed* polarity to cancel the initial voltage, as shown in Fig. 73*d*.

Figure 74 shows a circuit in which such a shorted-end line may be used to develop a short pulse from a longer input pulse. When V_1 is suddenly made conducting by a wide input pulse, a negative voltage pulse appears at its plate for the duration of the round-trip delay of the line. The reverse occurs as the initial pulse ends. Tubes V_2 and V_3 may be used to clip the pulse by plate current cutoff so that only a rectangular pulse of the desired duration appears in the output. The approximate wave forms at each grid are shown. Tube V_3 acts as a cathode follower with low internal impedance and, therefore, has good regulation during the pulse.

(c) Circuit

(d) Pulse

FIG. 73. Pulse form in shorted-end delay network.

77. The Blocking Oscillator. The blocking oscillator is a special form of sine-wave, or inductively coupled, oscillator, one in which the feedback is so large during the major portion of the conducting cycle that a large amount of grid current is drawn, damping the sine wave and storing sufficient charge in the grid capacitor to ex-

tinguish conduction after a single distorted cycle has been developed. Initiation of the blocking oscillator is dependent on the rate of change of voltage in the initiating pulse, with the result that accurate triggering is even more dependent on pulse shape than it is in an MV.

A typical circuit for a blocking oscillator is shown in Fig. 75. Proper operation is critically dependent on the existence of a source of stored energy, usually the capacitor C_s shown in Fig. 75, connected from the cathode of the tube to the supply end of the plate winding of the transformer. Either absence of the capacitor or the use of a smaller capacitor than is required causes erratic operation.
FIG. 74. Pulse forming by shorted-end delay network.

The blocking oscillator develops its pulse through damping and amplifier saturation. Either the first half cycle or the first positive overshoot of the plate voltage due to transformer resonance may be used directly with the blocking oscillator to modify the grid or plate supply voltage as required. The pulse shape is then somewhat rounded, and better results are obtained after clipping in a driving tube. An iron-core pulse transformer couples the plate to the grid in proper polarity for oscillation, which is prevented between pulses by a large negative grid voltage. The output load is coupled from the same transformer. The plate current is abruptly increased by regenerative action when the grid voltage is made sufficiently positive, thereby initiating a half cycle of violent oscillation. Bias voltage is produced thereby to prevent further regenerative operation until again triggered.
FIG. 75. Blocking oscillator.

The voltage on C_2 in Fig. 76 is increased at each trigger pulse through C_1 and diode V_1 by an amount equal to $C_1/(C_1 + C_2)$ times the difference in voltage of the pulse and the voltage which is on C_2 immediately preceding the pulse. The tap for the cathode of blocking oscillator V_3 may be adjusted so that one or more input pulse steps are required to raise the grid potential above plate-current cutoff, thereby providing operation at the trigger repetition frequency, or some submultiple thereof. This expedient is useful where *division* of the repetition rate is desired, as, for example, when the average load in the equipment corresponding to a low repetition rate must not be exceeded. The first half cycle of a violently regenerative oscillation is started when plate current flows. Grid current is then drawn through diodes V_1 and V_2 in series, discharging C_2 so that the oscillation is not repeated until triggered again.

The grid current during each initial half cycle of the blocking oscillator of Fig. 77 charges C_1 to such a voltage that the tube then remains cut off for a considerable interval, depending on the time required to discharge C_1 through R_1 and R_2 in parallel. This determines the repetition rate and no trigger pulse is needed. Plate current is terminated at the end of

each half cycle, and the first positive overshoot of plate voltage due to transformer resonance provides the useful output. This allows considerable storage of energy $(LI^2/2)$ in the field of the transformer, which develops a voltage somewhat less than $I\sqrt{L/C}$ during the first damped half cycle after plate-current cutoff. The pulse duration is determined by the transformer inductance and circuit capacitance.
FIG. 76. Triggered blocking oscillator.

78. Termination of Pulse in Oscillator Circuit. The circuit for the supply of grid or plate voltage to triode r-f oscillators may be so arranged that the duration of the pulse, when once triggered, is determined in the oscillator circuit itself. Such arrangements are used at low power and where the pulse shape is not critical.
FIG. 77. Self-pulsed blocking oscillator.

Figure 78 shows a circuit for a triode oscillator in which the pulse length is determined by a combination of the time constants of the grid circuit of the driving tube V_1 and of the cathode circuit of the oscillator V_2. The cathode of V_2 is maintained at a sufficiently high potential between pulses by the bleeder to prevent the flow of plate current. The leading edge of the input pulse raises the oscillator grid voltage and initiates oscillation. C_2 then charges slowly to raise the cathode voltage while the grid supply voltage falls as the charge
FIG. 78. Time constants of supply circuits determine duration.

on C_1 leaks off through R_1. After an interval which may be adjusted by changing C_1, R_1, or C_2, the tube can no longer oscillate and the pulse is terminated.

Figure 79 shows a circuit for a triode oscillator in which the pulse length is determined by an open-end delay network in the cathode circuit. Tube V_2 is biased beyond plate-current cutoff between pulses and is started by a pulse slightly wider than desired, applied to the driver V_1. The average oscillator cathode current initiates a pulse in the cathode delay network which is reflected from its open end with the same polarity and is returned to the cathode to raise its potential and terminate the pulse.
FIG. 79. Pulsed triode with delay line determining duration.

Alternatively, a delay network may be used in the grid circuit. In this case, a pulse of voltage negative relative to the grid is initiated by the grid current at the start of oscillation. The pulse travels to the end of the line and returns with the same polarity to bias the grid beyond plate-current cutoff and terminate the pulse.

THE CALCULATION OF DISTORTION

The calculation of amplitude distortion may be accomplished in at least three different ways. The first of these techniques, based on either the Fourier sum or, for nonrepetitive wave forms, the Fourier integral, is used with the output wave form itself in the time domain. The second is based on the Legendre polynomial expansion of the input-output relation of the device, and resolves the distortion in terms of orthogonal polynomials; it may be applied to devices having single-valued input-output relations, and also may be applied to devices having two outputs for each value of input as long as the load contour possesses central symmetry. (Such contours as ellipses and cyclic hysteresis loops have such symmetry.) The third is the use of some simple equations applying to many of the more common electronic circuits.

79. The Fourier Technique. The Fourier-series technique for the evaluation of harmonic content of a wave form takes advantage of the fact that trigonometric functions of different frequencies are orthogonal, that is, the integral

$$\int_0^{2\pi} \sin nt \sin (mt + \phi)\, dt \equiv 0 \tag{72}$$

holds identically when $n \neq m$ and when $\phi = 90$ deg. A corresponding integral involving cosines also holds exactly when $n \neq m$ and when $\phi = 90$ deg:

$$\int_0^{2\pi} \cos nt \cos (mt + \phi)\, dt \equiv 0 \tag{73}$$

As a consequence of these relations, any repetitive wave form may be resolved into harmonically related sine and cosine components which, when combined in an adding circuit, will reproduce the original wave form.

A resolution by Fourier analysis does not yield a unique solution because a simple phase shift of the wave form being analyzed will yield a completely new set of frequency components. For that reason, it is usually convenient to place the origin

of time at a point which will give either mirror symmetry or reversed mirror symmetry as in Fig. 80. If mirror symmetry can be used about the time origin, then only cosine functions need be considered; in reversed symmetry, only sine. If neither can be used, then both sine and cosine functions are required for the complete solution.
FIG. 80. Symmetry relations of periodic waves.

When analytical expressions for the waves are available, the integrals below may be used to find the Fourier coefficients a_n and b_n:

$$a_n = \frac{1}{\pi}\int_0^{2\pi} f(u)\sin nu\,du \tag{74}$$

$$b_n = \frac{1}{\pi}\int_0^{2\pi} f(u)\cos nu\,du \tag{75}$$

where the actual wave form when expanded in terms of the coefficients gives

$$f(u) = \frac{b_0}{2} + \sum_{j=1}^{\infty} b_j \cos jx + \sum_{j=1}^{\infty} a_j \sin jx \tag{76}$$

These expressions assume that the original wave has at most a finite number of discontinuities over the range $-\pi$ to $+\pi$ (or 0 to 2π); the value represented by the expression at the discontinuities is half the sum of the values on either side.

Fourier series do not always converge uniformly; for example, representations of square waves and rectangular-pulse waves provide only poor approximations to the function near the discontinuities. Convergence can sometimes be improved by the use of Fejer polynomials.[1]

FIG. 81. Square wave.

FIG. 82. Triangular wave.

FIG. 83. Saw-tooth wave.

80. Some Typical Expansions. Some of the more commonly useful Fourier expansions are listed below, together with their associated wave shapes:

Square wave (Fig. 81)

$$e = \frac{4E_0}{\pi}\left[\cos\theta - \frac{\cos 3\theta}{3} + \frac{\cos 5\theta}{5} + \cdots + \frac{(-1)^n\cos(2n+1)\theta}{2n+1} + \cdots\right] \tag{77}$$

Triangular wave (Fig. 82)

$$e = \frac{8E_0}{\pi^2}\left[\cos\theta + \frac{\cos 3\theta}{9} + \frac{\cos 5\theta}{25} + \cdots + \frac{\cos(2n+1)\theta}{(2n+1)^2} + \cdots\right] \tag{78}$$

Saw-tooth wave (Fig. 83)

$$e = \frac{2E_0}{\pi}\left[\sin\theta - \frac{\sin 2\theta}{2} + \frac{\sin 3\theta}{3} - \frac{\sin 4\theta}{4} + \cdots + (-1)^{n-1}\frac{\sin n\theta}{n} + \cdots\right] \tag{79}$$

Fig. 84. Pulse train.

Fig. 85. Half sine wave.

Fig. 86. Rectified sine wave.

Clamp reference

Sine wave reference
Fig. 87. Clamped sine wave.

Short rectangular pulse (Fig. 84)

$$e = E_0\left[k + \frac{2}{\pi}\left(\sin k\pi \cos\theta + \frac{\sin 2k\pi \cos 2\theta}{2} + \cdots + \frac{\sin nk\pi \cos n\theta}{n} + \cdots\right)\right] \tag{80}$$

Half-wave rectifier output (Fig. 85)

$$e = \frac{E_0}{\pi}\left[1 + \frac{\pi \sin\theta}{2} + \frac{2\sin 2\theta}{3} - \frac{2\cos 4\theta}{15} + \cdots + (-1)^{\frac{n}{2}+1}\frac{2\cos n\theta}{n^2 - 1} + \cdots\right] \tag{81}$$

Full-wave rectifier output (Fig. 86)

$$e = \frac{2E_0}{\pi}\left[1 + \frac{2\cos 2\theta}{3} - \frac{2\cos 4\theta}{15} + \cdots + (-1)^{\frac{n}{2}+1}\frac{2\cos n\theta}{n^2 - 1} + \cdots\right] \tag{82}$$

Biased diode (Fig. 87)

$$e = \frac{cE_0}{\pi}\left(\sum_{j=1}^{\infty}\left\{\frac{\sin[(n-1)\arccos a/c]}{n-1} + \frac{\sin[(n+1)\arccos a/c]}{n+1} - \frac{2a\sin[n\arccos a/c]}{nc}\right\}\right) \tag{83}$$

81. Graphical Analysis. The graphical analysis of wave forms is accomplished by dividing the basic period of repetition into $2m + 1$ equal increments of time and then establishing a series of algebraic equations, one for each of the selected time points, in terms of the harmonic components. For example, the value of the function or wave at the instant j may be written as

$$x_j = b_0 + \sum_{k=1}^{m} a_j \sin\frac{\pi jk}{m} + \sum_{k=1}^{m} b_j \cos\frac{\pi jk}{m} \tag{84}$$

where k is the order of the harmonic and j identifies the specific one of the $2m + 1$ increments of the period at which the data apply. Consequently, substitution of the appropriate values for x_j, $\sin(\pi jk/m)$, and $\cos(\pi jk/m)$ for the appropriate points in this equation and making one equation for each value of j gives a set of $2m + 1$ equations which can be solved for the coefficients a_k and b_k.

82. Legendre Polynomial Expansions. Distortion components can also be calculated from an amplifier input-output function or the input amplification function (the functions expressing the output or the amplification in terms of the input) by the use of Legendre polynomials, giving

$$f(s) = \sum_{j=0}^{\infty} c_j P_j(s) \tag{85}$$

The function $f(s)$ represents a set of values of the output voltage or the amplification at a series of discrete values s of the input voltage.

First the set of data being analyzed is evaluated at a series of equal increments of the input variable, the input voltage, and the standard technique is used for fitting a set of Legendre polynomials through the data representing the function. Briefly, the steps are:

1. Tabulate as a function of s the values of the input voltage e_i at which values of the function are available, where s is the number of increments displaced from the initial point.
2. Tabulate the function values $f(s)$ at the points s.
3. Write the values of the polynomials from the tables.[1]
4. Sum the squares of the polynomial values for given j as a function of the parameter s.
5. Sum the product of $f(s)P_j(s)$ for given j as a function of s.
6. Find the quotient of the values (5) divided by the corresponding values (4).

A typical analysis of the Legendre expansion of a function of amplification can be tabulated as in Table 5.

Table 5

e_i	s	$K(s)$	$P_0(s)$	$P_1(s)$	$P_2(s)$	$P_3(s)$	$P_4(s)$
e_{i0}	0	$K(0)$	$P_0(0)$	$P_1(0)$	$P_2(0)$	$P_3(0)$	$P_4(0)$
$e_{i0} + e$	1	$K(1)$	$P_0(1)$	$P_1(1)$	$P_2(1)$	$P_3(1)$	$P_4(1)$
$e_{i0} + 2e$	2	$K(2)$	$P_0(2)$	$P_1(2)$	$P_2(2)$	$P_3(2)$	$P_4(2)$
$e_{i0} + he$	h	$K(h)$	$P_0(h)$	$P_1(h)$	$P_2(h)$	$P_3(h)$	$P_4(h)$
S_j			$\sum_{h=0}^{n} P_0^2(h)$	$\sum_{h=0}^{n} P_1^2(h)$	$\sum_{h=0}^{n} P_2^2(h)$	$\sum_{h=0}^{n} P_3^2(h)$	$\sum_{h=0}^{n} P_4^2(h)$
B_j			$\sum_{h=0}^{n} K(h)P_0(h)$	$\sum_{h=0}^{n} K(h)P_1(h)$	$\sum_{h=0}^{n} K(h)P_2(h)$	etc.	
C_j			$P_0(n)B_0/S_0$	$P_1(n)B_1/S_1$	$P_2(n)B_2/S_2$	etc.	

As can be seen, the C_js are the coefficients of the polynomials in Eq. (85). The values of the P_j functions are tabulated in many books on numerical analysis in addition to Milne; the values for a few cases are given in Table 6. The data have been reduced to corresponding integral values, since the divisors can be shown to cancel out in the process of analysis.

83. Calculations with Legendre Polynomials. The Legendre coefficients may be converted directly into the amplitudes of the harmonic components by the use of conversion equations.

The set for converting the data on amplification as a function of input bias is

$$\begin{aligned} E_5 &= K_4/80 = 35C_4/640 \qquad E_4 = K_3/32 = 5C_3/64 \\ E_3 &= -K_2/12 - K_4/16 = (15C_4 - 48C_2)/384 \\ E_2 &= -(2K_1 + K_3)/8 = (C_3 - 4C_1)/16 \\ E_1 &= K_0 + K_2/4 + K_4/8 = C_0 - C_2/8 - C_4/64 \end{aligned} \tag{86}$$

where the various E_j apply to the equation

$$e = E_0 + E_1 \sin \omega t + E_2 \sin 2\omega t + E_3 \sin 3\omega t + \cdots + E_j \sin j\omega t + \cdots \tag{87}$$

and the C_j are obtained from the equation

$$K = \sum_{j=0}^{m} C_j P_j(s) \tag{88}$$

[1] See the included tables and also Milne, "Numerical Calculus," p. 375, Princeton University Press, 1949.

Table 6. Table of Values of Legendre Polynomials

+3	+7	−7	−21	−11	7	+2	−6	−23	−1	+4
+4	+28	+14	+14	+4	8	+3	−1	−22	−6	−1
					9	+4	+6	−6	−6	−6
					10	+5	+15	+30	+6	+3
60	2,772	990	2,002	468	S_j	110	858	4,290	286	156

The columns P_0 have been omitted for $n = 8$ and $n = 10$ since each value in the column is positive unity, and the sum S_j is $n + 1$.

The set of equations for converting the data on output voltage as a function of the input voltage is:

$$\begin{aligned} E_5 &= 63C_5'/128 \qquad E_4 = 35C_4'/64 \qquad E_3 = -5C_3'/8 - 35C_5'/128 \\ E_2 &= -3C_2'/4 - 5C_4'/16 \qquad E_1 = C_1' + 3C_3'/8 + 15C_5'/64 \\ E_0 &= C_0' + C_2'/4 + 9C_4'/64 \end{aligned} \tag{89}$$

where the E_j are defined in Eq. (87), and the C_j' are the coefficients of the equation

$$e_0 = \sum_{j=0}^{n} C_j' P_j(s) \tag{90}$$

These two sets of equations give the amplitudes of the respective harmonic components in terms of the coefficients of the corresponding Legendre polynomials.

84. Bivalued Contours. A similar technique may be applied to elliptical or other load lines having central or radial symmetry, giving both the in-phase and the quadrature components of the various harmonics present in the output wave. The analysis is divided into two parts, (1) the calculation of the equivalent in-phase components, corresponding roughly to the magnetization curve with the hysteresis loop (Fig. 88), and (2) the reduction of the asymmetrical excursions into quadrature components. With Legendre polynomials, the first operation is to fit a fifth-order set of polynomials to the contour or load line over one-half of its cycle, such as branch

A in Fig. 88. The symmetrical portion of this set of polynomials consists of the odd-order group (based on the input-output relation as the contour). The even-order polynomials may then be replotted, using one extreme point (e.g., *C*) as the center, and taking a reverse polarity or sign for the polynomial values on one side of the new center point (Fig. 89). The resulting contour may then be reanalyzed in terms of odd-order polynomials. In this analysis, however, a new set of data points must be taken, these points being related to the set used in the first step in accordance with Table 7, where the $\Delta e = (E_{cp} - E_{cs})/n$, with E_{cp} being the most positive bias voltage in the cycle, E_{cs} the static value of voltage, and n being the total number of data points used per quadrant. Use of the listed data points assures uniform spacing and proper symmetry for the replotted quadratic terms.

Fig. 88. Hysteresis loop.

Fig. 89. Components of bivalued input-output relation.

Table 7. Table of Data Points for Reduction of Elliptical Contours

Symmetric points		Asymmetric points	
Angle	Voltage	Angle	Voltage
arcsin 0	0	arccos 0	$n\Delta e$
arcsin $1/n$	Δe	arccos $1/n$	$\Delta e \sqrt{n^2 - 1}$
arcsin $2/n$	$2\Delta e$	arccos $2/n$	$\Delta e \sqrt{n^2 - 4}$
arcsin $3/n$	$3\Delta e$	arccos $3/n$	$\Delta e \sqrt{n^2 - 9}$
.	.	.	.
.	.	.	.
.	.	.	.
arcsin 1	$n\Delta e$	arccos 1	0

The correctness of the results may be readily verified by checking through the expansion of any bivalued function having central symmetry. The functions to be summed in terms of phase angles are:

$$E_1 \sin t$$
$$E_1' \sin (t + 90°)$$
$$E_3 \sin 3t$$
$$E_3' \sin (3t + 90°)$$
$$E_5 \sin 5t$$
$$E_5' \sin (5t + 90°)$$

where the unprimed *E*s are the amplitudes of the trigonometric components from the symmetric or odd polynomials, and the primed *E*s are the amplitudes of the trigonometric components from the asymmetric or even polynomial components after they have been converted to odd-order polynomials.

85. Equations for Distortion. In addition to the analytic techniques for evaluating distortion, techniques for rapid approximation of amplifier distortion have been used for many years. Some of these equations are expressed in terms of averaged amplification (strictly a voltage change), and others in terms of the actual small-signal amplifications. Where the required data are available, the expressions in terms of

small-signal amplification give the user more complete understanding of the problem, with the result that they are somewhat more satisfactory.

Second Harmonic Distortion. The approximate equation in terms of averaged amplification or voltage change is

$$D = 50(E_{bn} + E_{bp} - 2E_{bs})/(E_{bn} - E_{bp}) \tag{91}$$

In this equation, E_{bn} is the plate voltage at which the grid voltage is most negative, E_{bp} the plate voltage at which the grid is most positive, and E_{bs} the static plate voltage. The distortion D given in Eq. (91) is the approximate percentage of second harmonic generated.

In terms of small-signal amplification, Eq. (91) may be written in the form

$$D = 25(K_p - K_n)/(K_p + K_n) \tag{92}$$

In this equation, K_p is the amplification at the positive bias limit, and K_n the amplification at the negative bias limit.

Third Harmonic. If the distortion is primarily third harmonic, as it is, for example, in a properly balanced push-pull amplifier, the determination of the distortion requires data on the amplification at the static bias point (K_s) in addition to the two limit points. The equation for the third harmonic distortion with $K_p = K_n$ then is

$$D = 100(K_s - K_p)/3(3K_s + K_p) \tag{93}$$

If K_p and K_n are nearly, but not exactly, equal, then the equation reads

$$D = 100(2K_s - K_p - K_n)/3(6K_s + K_p + K_n) \tag{94}$$

MISCELLANEOUS NONLINEAR CIRCUITS

86. Nonlinear Elements in AVC and AGC. Amplifiers which amplify a wide range of signal voltages and provide a relatively constant output signal are expected to do so with a minimum of distortion. A smooth variation of amplification as a function of a control voltage is the characteristic required of the tube used in this application. The ratio of the change in amplification to the average amplification should be proportional to the signal voltage and relatively independent of the static bias applied. Or $\Delta K/K_0 = c\Delta e_c$, and integrating, $\log (K/K_0) = ce_c$, where K is the amplification at the bias e_c, K_0 is the maximum amplification, and c is an arbitrary constant.

Although amplifiers having logarithmic characteristics are by no means distortionless, on the average they can provide the required variation in amplification with comparatively small distortion. Tubes which are used for logarithmic amplifiers are called *remote-cutoff* tubes. Although pentodes such as the 6BA6, the 6BJ6, and the 6SK7 usually are used in this service, some dual triodes for use as cascode amplifiers have recently been introduced. The 6386 is such a tube.

The variable-gain amplifier is normally used in r-f or i-f circuits of communication equipment. The different values of amplification are selected by the use of an AVC circuit, which meters the incoming signal voltage and returns a bias to the amplifiers to hold the average output voltage reasonably constant. To prevent excessive distortion, usually only a very small part of the AVC control signal is applied to the final amplifier. As a result, most of the control is obtained in the early stages of the receiver.

87. AVC Control Circuits and Amplifiers. The circuit providing the control for an AVC amplifier may return a voltage which is approximately proportional to the average signal at the detector, or it may have no effect until a certain chosen signal level is reached (*delayed AVC*). Best results with delayed AVC are obtained if a separate, constant-gain, final amplifier is used to provide the control signal to the AVC detector; with a proportional AVC system, the signal detector may be used for AVC as well as signal detection if desired. The separate amplifier is required to prevent clipping distortion from being generated on the modulation.

Additional amplification, either before or after detection, may be used with delayed AVC to hold the output-signal variation to a minimum. The isolating amplifier can

also contribute substantially to improving the constancy of gain. Since a voltage gap of 1 or 2 volts minimum is desirable to provide for effective delay on the AVC action, the extra amplification is usually included in the i-f portion of the system. A d-c amplifier can be helpful after detection if a suitable negative supply is available to power it. Average output-signal-level variations of as small as 10 per cent may result with a change of input-signal level of 40 to 60 db in properly designed AVC amplifier systems.

88. Design of Amplifiers. The design of variable-gain amplifiers, because of the amplification range over which the coordination of static and small-signal data is required, is best accomplished with the help of a logarithmic type of screen-characteristic data sheet for the tube which includes small-signal data. A sheet such as
FIG. 90. Screen characteristics, 6BJ6.

that shown in Fig. 90 has proved useful for the application, since the range of bias and small-signal characteristics required to design the amplifier is available in addition to an adequate distribution of the data on the plate current. The transconductance contours are plotted on a decade basis to simplify the calculations at the widely varying conditions encountered.

In the design of an i-f amplifier, the steps required after the selection of a suitable tube with its appropriate characteristic data include (1) the selection of the screen voltage to be used (or the minimum screen voltage if a series screen supply such as that shown in Fig. 91 is used), (2) the selection of the maximum amplification desired per stage (usually 20 or less where stability is of prime importance), and (3) the design of the required AVC supply circuits. A typical circuit is shown in Fig. 91. After the screen voltage has been selected, a screen load line may be plotted; it is represented by a vertical line at the appropriate voltage if a fixed screen supply is used, or it may be calculated from the equation

$$e_{c2} = E_{cc2} - I_p X_{c2} R_s \qquad (95)$$

where E_{cc2} = screen-supply voltage
e_{c2} = screen voltage
I_p = nominal plate current
X_{c2} = screen-current-division factor (see Sec. 15)
R_s = series resistance between screen and screen supply

The values of I_p and X_{c2}, in addition to X_p and G_{m1}, may be read directly from the screen-characteristic curve sheet. After these data are tabulated, the characteristics of the amplifier stages as a function of the control voltage may be calculated, after which the over-all characteristics of the amplifier may be obtained by selecting a series of output voltages, finding the corresponding control voltage, and calculating successively the inputs to the individual amplifier stages, starting at the output. The distortion may be checked at the same time. The gain of the individual amplifier stages may be found from the equation

$$K = -G_{m1}X_pZ_L \qquad (96)$$

where Z_L is the tuned impedance and G_{m1} and X_p are obtained from the curve sheet.

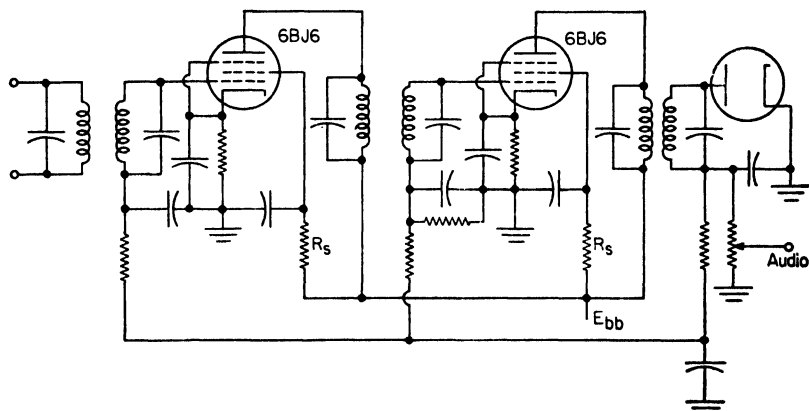
89. Linear Time Variant (LTV) Circuits. Circuits in which the variations in small-signal parameters are a function of some input or control signal other than the principal signal being processed are not in the strictly mathematical sense nonlinear


Fig. 91. Typical i-f amplifier.

although they behave in a manner similar to circuits which are nonlinear. The behavior is described as linear time variant (LTV) since, if the control signal, which is usually time-dependent, is held at a constant value, the operation of the amplifier would be completely linear. On an instant-by-instant basis, therefore, the theorem of superposition and other criteria governing the action of linear circuits are applicable to LTV circuits.

The variation of the circuit characteristics is usually obtained through the use of a control voltage or current which is periodic in nature (often a sine wave). This control signal must have an amplitude which is large compared with that of a signal whose characteristics it is altering in step with the control. The result is that an LTV circuit acts as an electronic multiplier, multiplying the received signal by the control signal alone without permitting components of the received signal to be multiplied by each other.

90. Mixers as LTV Circuits. Mixer circuits are probably the most commonly used form of circuit having LTV characteristics. They possess the LTV property as long as the received signal is small in amplitude in comparison with the local oscillator signal. If the received signal can be amplified by the mixer with negligible distortion in the absence of the local oscillator signal, adequate linearity is available

to assure LTV operation. Although operating conditions usually are such that the assumption is valid, in the presence of either noise of excessively high amplitude or a strong interfering signal, the behavior may not be linear time variant with a mixer.

91. The Autocorrelation Detector. The autocorrelation detector is a form of LTV circuit using a mixer as a multiplier in which the received signal is divided into two parts and then introduced after separate processing to the two multiplier inputs. One of the parts of the signal goes directly to one input, and the other is passed through a delay circuit which delays the signal and noise for a sufficiently long period of time to permit the noise in the two parts of the signal to become random with respect to one another prior to its introduction to the second input. The components of the desired signal, because of its periodic nature, still maintain a coherent relation in spite of the delay, with the result that the noise tends to cancel, whereas, with correctly selected delay, the components of the desired signal reinforce one another. A typical circuit is shown in Fig. 92.

92. The Cross-correlation Detector. The cross-correlation detector differs from the autocorrelation detector primarily in the form of the signals used in the input channels. Two signals, the received signal and a processing signal, are applied to the two inputs of the LTV circuit. The characteristics of the received signal are usually known only in general form rather than in detail. The second, or locally generated signal, either may be very similar in nature to the desired signal, in fact a
FIG. 92. Autocorrelation circuit.
FIG. 93. Phase detector.

complementary signal if the equipment designer can produce one, or it may have characteristics which will facilitate recognition of the received signal. Often all that is required of the local signal is that its frequency be as nearly as possible exactly the same as that of the carrier of the received signal; if, however, the intelligence is actually conveyed by the carrier itself instead of the modulation, then a frequency offset of a few hundred or a few thousand cycles may provide better operating conditions.

One of the commonly used forms of cross-correlation detector is the phase detector (Fig. 93). This device can be used to keep two frequencies exactly in step, and in fact to maintain quadrature between the received signal and the local signal to within a few electrical degrees. The d-c output from the phase detector may be used both as a control voltage to keep the correct phase relation and also to give a signal which is proportional to the frequency deviation (or modulation). Further discussion of the action may be found in Sec. 60.

93. Regenerative Cross-correlation Detector. The regenerative detector, when used with weak input signals, behaves similarly to a cross-correlation detector because of the control exerted by the local oscillations. As the circuit is ordinarily built (Fig. 31) the variable grid loading makes operation somewhat nonlinear, with the result that the inherent characteristics of the detector often are not adequately utilized. If, however, circuits such as those shown in Fig. 32*a* and *b* are used, then the operating characteristics with small signals are rather linear, with the result that the high Q of the tuned circuit may be utilized effectively, and the circuit behaves largely as a cross-correlation detector. The local oscillation actually serves two purposes, first to build up the effective Q of the tuned circuit to produce, in effect, linear passive amplification of the signal, and to introduce correlation detection after the amplitude is sufficiently large.

94. Signal-to-noise (S/N) Characteristics of Detectors. One of the properties of particular concern in any type of detector, whether it is piecewise-linear, nonlinear, or time-variant, is its ability to separate the desired incoming signal from the combination of signal and noise. Representing symbolically the combination of signal and noise as $[S] + [N]$, the output from either the piecewise-linear detector or the nonlinear detector takes the form.

$$[S][S] + [S][N] + [N][S] + [N][N] \tag{97}$$

and can be reduced to the form

$$[S][S] + 2[S][N] + [N][N] \tag{98}$$

If this equation is reorganized to give S/N, it takes the form

$$S/N = [S]/(2[N] + [N][N]/[S]) \tag{99}$$

since both the last two terms in Eq. (98) constitute noise terms. As can be seen, the noise components in the denominator have at least twice the amplitude they have in the incoming signal. If the signal is appreciably stronger than the noise, then the signal-to-noise ratio is cut in half, whereas if the noise is large compared with the signal, then the signal will be embedded deeply in the noise. Consequently, nonlinear types of detectors are poor weak-signal detectors.

95. S/N Characteristics of Autocorrelation Detector. With the autocorrelation detector, an action similar to ordinary detection takes place, the one difference being that the noise carried with the two signals being multiplied in the detector differs appreciably at the two inputs because of the time delay introduced in one channel. If the delay is sufficient, the noise in the two channels becomes uncorrelated, with the result that Eq. (98) becomes

$$[S]([S] + [N] + [N^0]) + [N][N^0] \tag{100}$$

Now, since $[N]$ and $[N^0]$ are uncorrelated, their sum is not $2[N]$ but a number less than it. On the average, statistically, the sum with random noise has the value $\sqrt{2}\,[N]$; at the same time the term $[N][N^0]$ will have a value less than $[N][N]$ because of the statistical averaging. Approximately 3 db of improvement in signal-to-noise ratio is obtained by the use of an autocorrelation detector in place of a nonlinear detector.

96. S/N Characteristics of Cross-correlation Detector. The cross-correlation detector requires a somewhat different form of equation than the autocorrelation because of the locally generated control signal. Identifying the control signal as $[S^0]$, the output takes the form

$$[S][S^0] + [N][S^0] \tag{101}$$

Unless noise or modulation is present on $[S^0]$, these are the only two terms present. Consequently, the output signal-to-noise ratio is

$$(S/N) = [S]/[N] \tag{102}$$

giving a post-detection signal-to-noise ratio which is identical with the predetection ratio; the cross-correlation detector, when used with a noise-free control signal $[S^0]$, then provides an output which is optimum as a signal-separation circuit.

The post-detection S/N for the cross-correlation detector, for band widths wider than the spectral width of the received signal, is inversely proportional to the square root of the band width, just as is the predetection ratio. On the other hand, nonlinear or piecewise-linear detectors have a post-detection S/N ratio which is inversely proportional to the fourth root of the band width, or definitely poorer than the predetection ratio. For this reason, the use of cross-correlation detection is indicated whenever quality is of greater importance than price in electronic equipment.

The significance of the data in the above paragraph is verified by the following results, which have been obtained in the microwave spectrum. King has reported

that well-designed superheterodyne receivers operating at K band have a sensitivity of approximately −130 dbw (db below 1 mw) with a conventional detector, −135 dbw with a rotating wave-guide phase shifter, and −140 dbw with a correlation, or synchronous, detector. The 10-db difference between the straight detector and the correlation detector as reported is consistent with the estimate of a minimum of 6-db improvement using correlation techniques. The phase shifter improves the characteristics somewhat by making the system partially time-variant and evidently makes the signal somewhat easier to recognize in the presence of noise.

Further data from the same source show that the use of a nonlinear detector directly without heterodyning and amplification is even poorer. If a 1N26 diode detector is used directly as a detector with a 4-cps audio amplifier, the system sensitivity is −100 dbw, and with a bolometer under similar conditions −90 dbw. These data show the low conversion or detection efficiency of the two detectors and their relatively high noise levels.

97. Noise-integration Techniques. Advantage can be taken of the lack of correlation in noise as compared with the desired signal to provide a random summation of the noise, and linear summation of the signal, thereby improving the over-all
FIG. 94. Transversal filter.

signal-to-noise ratio beyond the theoretical ideal obtainable without integration. Any type of time-delay filter may be used for noise integration by tapping the filter at equally spaced time delays, these delays corresponding to either half the period of the signal frequency or the full period. The use of a series of summing amplifiers at the respective taps, properly combined, causes the components of the desired signal to add at the output and the noise to tend to cancel (Fig. 94).

The reduction of noise may be understood by reference to the statistical problem of random walks, which states that, if n different random elements are added together, the probable average amplitude of the combination at the output is not the sum of the elements, but approximately

$$\bar{A} = \sqrt{n}\,\bar{x} \tag{103}$$

where n is the number of summations and $\bar{x}$ is the average magnitude of the random elements without regard to polarity (the average of the absolute values).

The time delay, or transversal filter,[1] as it is sometimes called, is only one of a number of devices which can be used for noise integration. Among some of the other techniques are cathode-ray integration, magnetic-tape or drum integration, etc. All these function by adding the coherent signal in phase and the noise in its own random phase, giving as a result an improved signal-to-noise ratio. Such devices are sometimes called *comb filters*.

CHAPTER 13

DIRECT-CURRENT AND LOW-FREQUENCY MEASUREMENTS

BY JOHN H. MILLER[1]

STANDARDS

1. General. True basic measurements of electrical quantities are rarely made except in standardizing laboratories, owing to the inherent difficulties in the procedure. Ordinary measurements are made by comparison devices of one form or another. Direct-reading instruments, having an electrical torque-producing means functioning against a spring, are calibrated against accurate standards which are in turn calibrated against basic measuring devices. Such torque-producing instruments are used for measuring current, voltage, power, and resistance. Instruments for measuring phase relations, frequencies, and other factors may have two torque-producing systems, each torque varying with the position of the moving element and bearing different functional relations to the quantity measured. The result is for the moving system carrying the pointer to take up a position where the torques balance, this being different for each different value of the quantity in question, and the scale may be marked accordingly.

Electrical units such as the volt, the ampere, and the ohm are based upon and are intended to be exact multiples of the units of the cgs electromagnetic system. The international units which were made standard in 1911 were derived according to the best procedures then available. However, refinement of measurement techniques in the years following, along with intercomparison of the units by the national laboratories of various countries, indicated that the international volt and ohm were larger than their absolute values by 0.0495 and 0.033 per cent, respectively. Accordingly, on Jan. 1, 1948, the absolute values were made standard and form the basis for all electrical measurements and instrument calibrations since that date.

2. Current. Current is measured, absolutely, in terms of the force of attraction or repulsion between two coils connected in series and carrying that current. More specifically, one cgs unit of current (1 abampere or 10 amp) flowing in a circuit consisting of two infinitely long parallel conductors causes a force of 2 dynes per cm length to act between them when they are 1 cm apart. From this basic definition to the particular case of the force between two coils in a current balance requires an integration of the total force of each element of each coil on the opposite coil. In turn this means extremely refined measurement of the several dimensions involved, *i.e.*, effective coil diameter, wire diameter, coil spacing, etc. The force developed between the coils for a given current is determined by balancing with known weights and in terms of the existing gravitational constant.

The use of the standard current balance is tedious and time-consuming, and determinations with it are made in the national laboratories only occasionally.

Actually the current balance as described is used for the calibration of a standard cell by balancing the voltage drop of the measured current through a known resistance against the potential of the cell. The standard of current is thus maintained through the application of Ohm's law, a standard of resistance, and the voltage of a standard cell.

[1] Weston Electrical Instrument Corp., a subsidiary of Daystrom, Inc.

3. Resistance. The ohm was defined in 1893 as the resistance of a mercury column 1 mm square and 106.3 cm long at 0°C. The ohm is presently determined in absolute terms by balancing the voltage drop of a current through the resistance in question against the rectified result of the a-c voltage induced in one coil of a mutual inductance, where the same current is commutated into the other coil. Balancing is accomplished by varying the commutating frequency. Thus the resistance is evaluated in terms of mutual inductance—a matter of coil dimensions—and frequency—a function of time. The standard ohm is now maintained by the National Bureau of Standards as the average of a group of 1-ohm manganin resistors, these units having been checked for their absolute values as described and having shown a change of less than 1 ppm from the mean of the group over many years. Practical secondary standards are coils of manganin wire immersed in oil and sealed in metal containers. Such sealed standards built by Leeds & Northrup to the specifications of the National Bureau of Standards are adjusted to an accuracy of 0.01 per cent and may be relied upon to hold their calibration to 1 part in 100,000 for considerable periods of time. The sealing of the containers is important to prevent the absorption, by the oil, of moisture from the atmosphere, for such moisture will deposit upon the shellac or other insulating material on the wire which, in turn, will cause mechanical strains to distort the values beyond normal expectancy.

4. Voltage. Voltage measurements cannot be made absolutely with an accuracy sufficient to make the measurement desirable, on account of the smallness of the electrostatic forces involved. The standard of voltage is maintained by the National Bureau of Standards as the average of a number of Weston *saturated* cadmium cells, sometimes known as the "Weston normal cell." The average value of this bank of cells is 1.018636 absolute volts at 20°C, and this value is cross-checked from time to time through the use of the standard ohm and the current balance as described above. These cells, as built by Weston and Epley, are correct to 0.001 per cent of the values given. The cell has a small but appreciable temperature coefficient, and in use its temperature must be maintained constant at the specified value. For this reason the saturated cell is not well adapted for commercial laboratory use.

The *unsaturated* cadmium cell, the type of standard cell customarily used for laboratory work, has a negligible temperature coefficient but must be compared with the saturated type for its initial calibration. Its voltage is constant to better than 1 part in 10,000, but the cells must be recertified yearly as the potential tends to drop very approximately 50 μv per year. Standard cells must always be used in a null fashion with no more than 50 μa drawn from the cell at any time.

5. Reactance. The self and mutual inductance of single-layer air-core coils and the capacitance of two-plate air capacitors having guard rings may be calculated from their dimensions, with an accuracy of better than 2 parts in 100,000. The standard of capacitance is maintained by the National Bureau of Standards as a bank of quartz-insulated air capacitors.

6. Frequency. The absolute standard of frequency is the mean solar day as measured by astronomical observations. At the present writing the International Committee on Weights and Measures is expected to adopt a definition of the second, as a unit of time, as "the fraction 1/31,556,925.975 of the tropical year 1900." The mechanical vibrations of quartz crystals provide standards of frequency when permanently connected into suitable vacuum-tube circuits and allowed to oscillate continuously at constant temperature. Their frequency is constant to 1 part in 10^9 per month and 1 part in 10^{10} per day for the best quartz standards. A variety of shapes of crystals have been used to attain freedom from the effect of minor temperature changes as well as changes in the constants of the associated electronic gear. Even with the best control of temperature and voltage there are short-time fluctuations of the order of 1 part in 10^{11}. The frequency of the crystal with which such accuracy may be obtained is near 100 kc for low-frequency types and 1 to 10 Mc for high-frequency types. By means of suitable multipliers and dividers all other frequencies may be obtained with the same accuracy.

Tuning forks made from carefully stabilized metals also provide frequency standards in conjunction with suitable tube circuits but usually of a lower accuracy; the best stability which has been reported is 1 part in 10^6 for several weeks.

Mention should also be made of the use of the constant properties of atoms and molecules as standards of frequency. For example, the use of the 3,3 inversion line of the ammonia molecule in the feedback loop of a stable oscillator will control the frequency to a value given by Shimoda as 23,870,131 kc. A cesium atomic beam has also been used in similar fashion.

Quartz crystals whose frequencies remain constant to better than 1 part in 10^6 may be made in the frequency range 20 kc to 75 Mc. Metals, such as nickel and certain iron alloys, having the property of magnetostriction, may be used as oscillators in suitable tube circuits. Their frequency range extends from 5 to 100 kc. Their stability is about 2 parts in 100,000. For the lower frequencies tuning forks and metal bars are used. Their frequency range is 25 to 1,000 cycles.

Reference is made to the summary paper by F. D. Lewis, Frequency and Time Standards, *Proc. IRE*, September, 1955, p. 1046. This paper includes a bibliography of 74 pertinent references.

CURRENT-MEASURING INSTRUMENTS

In the following discussion of electrical measuring instruments as such, and particularly of panel, switchboard, and portable types, a valuable reference is the American Standard, C39.1-1955, entitled "Electrical Indicating Instruments," obtainable from the American Standards Association, 70 East 45th Street, New York 17, New York. It is a very complete document with definitions of terms and standard requirements for the various classes of instruments which are adhered to by most makers.

Current-measuring instruments are discussed here in detail since most instruments basically respond to the level of current flow in their windings. Voltmeters are simply sensitive milliammeters with resistance units in series with the terminals and of such value that, at the marked full-scale potential, full-scale current flows through the resistance and actuating windings.

7. Moving-coil permanent-magnet instruments of the pointer type, or reflecting galvanometers, consist of a coil, usually wound on a metal frame for damping purposes, which can rotate in an intense uniform magnetic field produced by a permanent magnet.

The current I flowing through the turns N of the coil reacts with the magnetic field H in the air gap to produce a force F acting on each conductor proportional to the product IHl of the current, magnetic field, and length of conductor in the field. If the coil is pivoted at its center, a torque will be exerted, tending to rotate the coil about an axis parallel to the sides of the coil and perpendicular to the magnetic field. Some kind of restoring torque is provided which is proportional to the angle θ through which the coil rotates. Expressing the sensitivity S of the instrument as the angular deflection per unit current, it is given by
FIG. 1. Moving-coil galvanometer.

$$S = \frac{\theta}{I} = \frac{HNlb}{\tau} \tag{1}$$

where b is the diameter of the coil and τ is the restoring torque per unit angular displacement.

For maximum sensitivity a high flux density is desirable, although the effective upper limit appears to be about 4,000 gausses; higher values may act on otherwise imperceptible magnetic inclusions in the moving system and cause additional random torques which will give nonlinear deflectional characteristics. Further, since damping is a function of the square of the flux, high flux values may give overdamped deflectional characteristics even without a damping frame to the point where circuit damping

alone may require many seconds for a final reading. Sensitivity increase by flux increase alone is, therefore, of limited usefulness.

8. Torque to Weight Ratio. The torque should be as low as possible for high sensitivity. Suspended-type instruments show no friction, but low torque lengthens the period. Again there is a practical lower limit. In pointer-type instruments where the moving element rotates on pivots between sapphire or the more recent high-silica glass V jewels, there is a minimum torque which may be used for a given moving element weight in order that frictional effects will be unobservable. For instruments mounted on a switchboard and having a horizontal axis, the ratio of the full-scale torque in milligram-centimeters with the weight in grams should not be less than 40 for small instruments, 60 for larger instruments of 1 per cent accuracy, and still greater if greater accuracy is required. For portable instruments having a vertical axis, it has been found that heavy elements, over 1 g, show greater friction than given by the above relation, and lighter elements show less friction. Hence for such vertical axis instruments for portable service the torque/weight$^{3/2}$ ratio is used and this ratio should be over 40 for small instruments and over 60 to 100 for large instruments for unobservable friction. Ratios much lower than this may be satisfactory for highly sensitive laboratory instruments used with care and not subject to vibration or handling.

9. Permanent Magnets. The magnetic field obtained from the permanent magnet must be constant so that the electrical characteristics of the instrument may remain unchanged. The constancy of a magnetic system is determined by the ratio K, which is equal to the product of the effective length of the magnet times the effective cross section of one of the air gaps, divided by the product of the cross section of the magnet and the total air-gap length. This constant should be over 100 for chrome and tungsten magnet steels and over 30 for high-cobalt steels. For the various nickel-aluminum or MK steels the constant will vary, but 10 may be taken as a median value.

Tungsten and chrome steels are still used to some extent, and although they result in relatively bulky structures, they still represent an inexpensive type of magnet for moderate flux densities. High-cobalt steels have been used but they are costly and have generally been replaced by various types of Alnico. Alnico V, in particular, both gives high flux density and can be used in a short length; its total energy content—the product of internal flux density and coercive force—is presently the highest available.

FIG. 2. Magnetic system (a) and cutaway view (b) of core-magnet mechanism.

Since the coercive values are very high, short magnetic systems are possible and in recent years the use of a core-magnet system has become quite prevalent. Figure 2a shows one form of such an arrangement where the internal magnet has sufficient energy to drive an adequate amount of flux through the gap to the surrounding ring structure and results in a very compact instrument mechanism as in Fig. 2b. Available structures give gap densities of 1,500 to 2,500 gausses in the air gap in conventional panel, switchboard, and portable instruments; in special structures where the magnet length can be somewhat increased, higher densities may be obtained.

An important quality of the core-magnet arrangement is its high degree of flux utilization. All the leakage flux is useful because the magnet is completely surrounded

by the moving coil, whereas the leakage flux with an outside magnet may be as much as 50 per cent. This again results in a smaller and more compact structure of lighter weight. Another important quality is that of self-shielding since the outer soft-iron ring or yoke not only serves as a return path for the main flux but also diverts extraneous flux around the air gap. More specifically, in a stray field of 20 oersteds which might be obtained from a conductor 1 ft away carrying 3,000 amp or, indeed, from an adjacent magnetron, an older model 1 portable instrument might be influenced as much as 10 per cent of its reading whereas with the new core-magnet structure the effect would be less than 0.3 per cent.

Where very high flux densities are needed they can be obtained with a massive external magnet. In special cases, densities as high as 9,000 gausses have been obtained over a narrow angle.

Where a distorted d-c scale is required to balance other factors, for example, to give an evenly divided scale marked in decibels, it is possible to cut the pole tips to produce a markedly distorted field resulting in a more useful scale for the quantity measured. It is more difficult, however, to manufacture such nonuniform pole pieces so that such instruments are inherently more expensive and the basic accuracy is usually somewhat less; cut-pole-piece instruments are quite widely used, however, because of the useful end result on the scale, and when hand-drawn scales are furnished the accuracy is usually adequate.

10. Deflection Indicators. The deflection of any sensitive galvanometer is indicated by the angular rotation of a beam of light, the so-called *optical lever*, which is reflected from a mirror, either plane or convex, mounted above the moving coil. The older form of telescope and scale is now being replaced by a spot of light containing cross hairs which moves along a scale. The use of a spot of light is much less fatiguing than observation through a telescope, and a wider range of view is obtained. The usual scale length is 50 cm with zero in the center. The standard distance from mirror to scale is 1 meter. The maximum angular deflection is about 14 deg. Practically all pivot instruments use pointers. Full-scale deflection corresponds to approximately 90 deg in the conventional types, which may be expanded to 120 deg in special cases.

11. Switchboard instruments and some panel instruments with deflection angles of 240 to 300 deg are becoming popular for power boards. Such instruments incorporate, for the moving-coil types, magnetic systems of the single-air-gap type; special vane arrangements are used for the moving-iron types. The large angle and resulting long scale lead to ease of reading. However, the necessity for compromise in the mechanism design to attain this wide angle of deflection usually limits the accuracy to 1 per cent. The requirement for increased power in the instrument, a limited frequency coverage in a-c instruments, and the necessity for using iron cores in the electrodynamometer types all combine to limit the use of this general form of instrument, and it is infrequently used in the electronic laboratory and in electronic gear.

12. Period and Damping. The moving element of every deflection instrument provided with a restoring torque proportional to the angular deflection is in effect a torsional pendulum. As such it has a moment of inertia P, a period T, and a damping factor. If the damping factor is low, the instrument will oscillate several times about its position of rest, each oscillation being less than the preceding one in accordance with the decrement of the system. For most rapid indication it is desirable that the instrument be not quite aperiodic or deadbeat but rather that it overswing from 3 to 5 per cent. (For a complete discussion of this see Forest K. Harris, "Electrical Measurements," Chap. 3, Equation of Motion, *et seq.*, p. 46, Wiley, 1952.)

Normal ammeters and voltmeters may be expected to have a period of the order of 1 to 2 sec. The smaller instruments, if equipped with magnets for very high gap densities and extremely light moving elements, may have a period as short as 0.2 sec (Weston high-speed power-level indicators). Instruments of ultrahigh sensitivity, where very little energy is available, may have a period as high as 5 sec. Sensitive suspension galvanometers may have a period as long as 12 sec.

The period of an instrument is important because the time necessary for any deflection instrument to attain a new position when its deflecting force is altered cannot be less than its period. High-speed indication in indicating instruments is very desirable, particularly when the phenomena being observed are rapidly changing, as in the monitoring of voice-frequency circuits; instruments with a long period will integrate the energy while high-speed instruments will give indications of peaks.

Air friction and residual pivot friction are not sufficient to prevent the moving coil from oscillating back and forth about its equilibrium position when a deflecting force is applied, and additional *damping* means must usually be provided. The amount of damping is measured by the rate at which the amplitude of the oscillations decreases. The ratio of any two successive swings is constant. The Napierian or hyperbolic logarithm of this ratio is called the *logarithmic decrement* of the instrument. The smallest amount of damping which will cause the coil to come to rest with no oscillation whatever is called the *critical damping*, and the coil is said to be critically damped. Increasing the damping beyond this point increases the time necessary for the coil to come to rest and produces overdamping. The shortest time in which the coil can come within a given small distance of its position of rest occurs when the coil is slightly underdamped. It has a value of about 1.5 times the period of the coil. The extra damping necessary to critically damp a coil is usually obtained magnetically from the motion of the coil in the field of the permanent magnet, which sets up counter electromotive forces. The amount of damping produced by the current in the coil depends upon the total resistance of the coil and connected circuit. That resistance which produces critical damping is called the *critical damping resistance* (CDR). A galvanometer is usually so designed that its critical damping resistance is at least five times its coil resistance so that it may be shunted for critical damping without losing much sensitivity. All but the most sensitive pivot instruments are damped on open circuit by the current set up in the metal winding form, and the resistance of the connected circuit has little effect on the damping.

13. The current sensitivity of any galvanometer varies directly as the number of turns on its moving coil and as the square of its period. For a given winding space on the coil, its resistance varies as the square of the number of turns, assuming that the portion of the winding space occupied by insulation remains constant. The deflection is proportional to the current and to the square root of the resistance, *i.e.*, to the square root of the power dissipated in the coil.

In the selection of galvanometers it should be noted that in general those of high sensitivity will also be slow in action, and in general the natural period and critical damping resistance for a galvanometer as listed by the several makers should be considered as carefully as the sensitivity. Further, galvanometers of highest sensitivity require great care in leveling; they are responsive to minor vibrations and in many installations may require special supports.

14. Galvanometer Supports. Where vibration in a building is a factor, the Julius suspension may be used, a somewhat complex system of weights supported by springs with oil-damping vessels. A simpler method although not so perfect is to rest a 200-lb block (of concrete) on an air cushion; this will absorb all vibration usually encountered in factories, at least for galvanometers of moderate sensitivity. Galvanometers with a single suspension have the greatest sensitivity, those with a taut suspension less, and those with double pivots least. For the most sensitive type of galvanometer, increasing the period from 5 to 40 sec allows the power to be decreased from 11 to 0.005 $\mu\mu$w. The minimum current sensitivity is 10^{-11} amp per mm. The smallest current sensitivity for a taut suspension is 10^{-8} amp per mm, and for a double-pivot pointer instrument, 5×10^{-8} amp per scale division.

15. Differential Galvanometer. Galvanometers of the suspended type are used mainly as null indicators for d-c bridges and potentiometers and as deflection instruments in comparison methods. In the latter case a *differential galvanometer* is sometimes used. This is a galvanometer having two separate insulated windings on the

* Sensitivity values of current I and voltage E are for a scale deflection of 1 mm at a scale distance of 1 m for suspended-coil galvanometers with mirrors; for those having self-contained scales the values given are for a deflection of the smallest division, usually 1 mm. Voltage values are on the basis of a circuit including the galvanometer and its external critical damping resistance, CDR, in series. System resistance is at the galvanometer terminals and includes both coil and suspension or spring resistance.

suspended coil. They have equal numbers of turns and are so connected that, when equal currents flow through the two coils, no deflection is produced.

16. Universal Shunt. The sensitivity of a galvanometer is most easily reduced by shunting, and, since it is desirable to keep the galvanometer critically damped, the Ayrton-Mather universal shunt shown in Fig. 3 is most convenient. This arrangement is also used in multiple-range ammeters and milliammeters and is frequently known as a "series shunt." The total resistance of the shunt is made approximately equal to the critical damping resistance of the galvanometer or indicating instrument with which it is used.
Fig. 3. Ayrton-Mather universal shunt.

17. D-c Ammeters and Voltmeters. Pointer-type instruments of the pivot type are used as ammeters and voltmeters of all ranges and as the indicating portions of thermocouple, rectifier, and various vacuum-tube instruments. The minimum range

of the ammeters extends from 5 μa to an upper limit determined only by the size of shunt desired, commercial shunts having been made to 50,000 amp. Above 15 to 30 ma the movements are shunted, in which case the copper or aluminum winding of the moving coil must have sufficient manganin swamping resistance in series with it to give a good temperature coefficient when shunted by the manganin resistance.

Alternatively, a low-resistance negative-temperature-coefficient resistor may be used in series with the moving coil, or as in the case of the more precise laboratory instruments, a shunt-series network of manganin and copper may be used for exact compensation over a selected ambient-temperature range.

Voltmeters may be made with a full-scale range from 1 mv to as high as series resistance can be arranged to care for the requirements. Instruments are made with self-contained series resistance up to a few hundred volts; higher ranges usually require an external resistor with the instrument placed in the grounded or low-potential side of the circuit for the sake of safety and to reduce electrostatic effects on the moving system.

Voltmeter sensitivity is very commonly 1 ma for full scale, although laboratory standards of certain types may take as much as 100 ma in the interest of a balanced design for high precision. Conversely, for analyzing electronic circuits where the networks are of high resistance, a full-scale value of 50 μa is quite common, giving 20,000 ohms per volt.

While series resistors for voltmeters have classically been of the wire-wound type to attain the required accuracy and stability, the advent of the pyrolytic carbon and borocarbon fixed resistors of superior characteristics has changed the picture and many panel instruments and test sets are now supplied with these types. If held to well within their rated dissipation limits for full-scale deflection they are usually satisfactory. Similar resistors incorporating thin metal films are also being used to a limited degree.

For ranges of over 1,000 volts tubular resistors are widely used incorporating wire-wound sections, each electrostatically shielded, assembled in insulating tubes and filled with inert wax.

Table 2. Voltmeters

Full scale, volts	Full scale, approximate ohms per volt	Approximate fixed resistance, ohms	Approximate 60-cycle impedance of rectifier and d-c instrument at full scale, ohms
150	1,000	149,400	600
50	1,000	49,400	600
10	1,000	9,400	600
4	1,000	3,400	600
3	2,000	4,860	1,140
2	2,000	2,800	1,140
1.5	2,000	1,860	1,140
1	5,000	3,050	1,950
0.5	5,000	550	1,950

18. Power Sensitivity. In general, pointer-type indicating instruments can be made to give full-scale deflection on as little as 0.1 μw, although for a rugged instrument from 1 to 5 μw is required. Moving-element resistances may be made from about 1 to 10,000 ohms. Low-resistance elements are limited by the spring or suspension resistance, which becomes a very appreciable part of the total, reducing the energy available for torque; high-resistance elements are limited by the available wire, and many are wound of enameled copper wire 0.001 in. in diameter.

19. Optimum Circuit Conditions. As in the output circuits of vacuum-tube amplifiers, the resistance of the instrument or galvanometer should be matched to the circuit in which it is placed for maximum energy transfer, and this is particularly

important where the energy is limited. On the other hand, this will frequently result in overdamping galvanometers of ultrahigh sensitivity, and a compromise must usually be made between speed of response and sensitivity requirements. It should be noted, however, that this matching is not of vital importance since the loss by an error in match by as much as 20 per cent is very small.

Table 3. Characteristics of A-c Galvanometers as Listed by Leeds & Northrup

* Sensitivity values of current I and voltage E are for a scale deflection of 1 mm at a scale distance of 1 m for the vibration galvanometers; for the pointer-and-scale type the current values given are per 1-mm division.

20. Moving-coil Vibration Galvanometers. When an alternating voltage is applied to the coil of a permanent magnet galvanometer, the coil will follow the alternations of the current if the frequency is of the same order as that defined by its period. Maximum amplitude of vibration will occur at the natural frequency of the coil. The relation between amplitude and frequency is similar to the resonance curve of an electrical circuit. The ratio of the maximum amplitude at its natural frequency to the amplitude for an equal d-c voltage is between 25 and 150. The period of the ordinary d-c galvanometer is never less than 1 sec, while the frequencies at which measurements are made are rarely less than 30 cps. The upper limit for a taut single suspension is around 300 cps. This limit may be raised to 1,000 by the use of a taut bifilar suspension. Electrical characteristics of commercial vibration galvanometers are given in Table 3. At 60 cycles their sensitivity is equal to that of a good d-c galvanometer. A resonance curve when tuned to a frequency of 100 cps is shown in Fig. 4.
Fig. 4. Resonance curve of vibration galvanometer.

The natural frequency may be raised still further by eliminating the coil entirely and using the single-turn loop formed by the bifilar suspension. The mirror is then placed at the center of the taut wires. The general method of construction is shown in Fig. 5. By this means a natural frequency of 12 kc may be obtained. The sensitivity decreases inversely as the first power of the frequency. On this account it is as sensitive at 10 kc as the bifilar-coil galvanometer was at 1 kc. In comparison with other null detectors at these frequencies, its sensitivity is so low that it is not much used in this form.

The Einthoven string galvanometer uses the simplest possible moving system for a galvanometer. A single conducting string moves in the narrow air gap of the magnetic system, which may be a permanent magnet or an electromagnet depending on the sensitivity desired. Its motion is observed through a microscope or by its shadow thrown on a screen from a point light source. The Einthoven string galvanometer built by the Cambridge Instrument Company uses a gilt glass fiber of 0.002, 0.003, or 0.005 mm diameter with a resistance of 6,000, 4,000, or 1,400 ohms, has a period of 0.0036 to 0.01 sec, and at 1 m will deliver deflections of 2 to 200 mm per μa. The string galvanometer may also be used as an oscillograph. The shadow of the string is observed on a translucent screen as reflected from a revolving mirror. The motion of the string may also be photographed on film or bromide paper. The usual paper speed is 10 in. per sec, but this may be increased to a maximum of 100 in. per sec. At this latter speed, phenomena lasting 1 msec appear 0.1 in. long.
FIG. 5. Bifilar suspension.

21. Moving-coil A-c Instruments. If a steady deflection is desired with a.c., the magnetic field must change in direction with the current in the coil and must have the same phase. This requires that the field be electromagnetic. In the case of galvanometers and particularly null indicators, a field of laminated iron may be used, excited at the same frequency as the moving coil. When used as a null indicator in a bridge network, the field is connected across the same supply as the bridge, while the moving coil is connected to the detector terminals. Since the current through the field and the flux produced will be nearly 90 deg out of phase with the voltage applied to the bridge, the galvanometer will be most sensitive to the reactance balance and will be little affected by the resistance balance. These conditions may be equalized or reversed by the introduction of resistance in series with the field, or reactance in series with the bridge, to make the field current and bridge current differ in phase by 45 deg or be in phase. The phase selectivity of the a-c galvanometer may be of advantage in certain special cases, but in general it is a considerable disadvantage. The electrostatic field of the main field winding exerts a considerable force on the moving coil so that it must be carefully shielded. The sensitivity of the a-c galvanometer is very high and it compares favorably with the best d-c galvanometers.

22. Electrodynamometer. When the iron core is omitted from the field winding, the moving coil and field coil may be connected in series. The deflection is then proportional to the square of the current flowing in the windings, and the instrument is called an *electrodynamometer*. Instruments of this type read the same on a.c. and d.c. and are suitable as transfer instruments, provided certain precautions are taken. Protection from external magnetic fields is most important. This is usually accomplished in pivot-type instruments by shielding with soft iron. It may also be effected by making the instrument *astatic*. When a.c. is used, an error is introduced if the distribution of current in the coils is affected by eddy currents in the conductors themselves—the so-called *skin effect*—or by capacitance between windings. The former effect is minimized by the use of conductors with insulated strands—so-called *litzendraht*—the latter by careful spacing and by electrostatic shielding.

Electrodynamometers may be used as galvanometers, ammeters, voltmeters, and wattmeters. Their sensitivity as galvanometers is so low compared with vibration galvanometers and other meters that they are now rarely used. As ammeters, voltmeters, and wattmeters, they are the standard instruments for use at commercial frequencies. In general the sensitivity of a-c instruments is of the order of 1/1,000 of that of d-c instruments, this being due to the difference in field intensity of the electromagnetic field as compared with that which can be obtained from a permanent magnet. Electrodynamometer instruments of the highest precision will take from 1 to 3 watts full scale, the total energy varying with the square of the deflection. Suspension-type electrodynamometers may have sensitivities 100 times as great.

Electrodynamometer ammeters have their fields and moving coils in series up to

several hundred milliamperes above which the moving element is shunted across a resistor in series with the fixed coils. Above 50 amp or so, current transformers are used, and these are now available with special alloy cores which will give accuracies of the order of ⅒ of 1 per cent. Note that low-range voltmeters have very low resistance in order to get the required energy; dynamometer voltmeters with full-scale values of 2 volts may draw as much as 0.5 amp. High voltages above 1,000 volts are measured with potential transformers.

Values of voltage *E*, current *I*, and power *W* are for full-scale deflection.

23. Electrodynamometer Wattmeters. When the field coils are connected in series with the load, and the moving coil of fine wire in series with a high resistance is placed across the load, the deflection is proportional to the product of the load voltage and the in-phase value of the current, or $EI \cos \theta$, or watts. For polyphase circuits a multiplicity of similar elements may be arranged on a single shaft, the most usual variety being the two-element instrument on three-phase circuits. Such an instrument gives true power without relation to phase angle.

24. Moving-iron Instruments. Galvanometers may be constructed with a stationary coil and a moving-iron vane or magnet. The moving system consists of small permanent magnets placed at the center of the coil at right angles to the axis of suspension. To avoid the effect of outside magnetic fields, the system is duplicated with the magnets pointing in the opposite direction to make it astatic, and the whole galvanometer is surrounded by multiple soft-iron shields. Its sensitivity is nearly equaled by the best moving-coil galvanometers so that it is very little used.

Soft iron may also be used in the moving element, either alone or in conjunction with a fixed piece of soft iron, both of which are magnetized by the fixed coil.

Soft-iron meters are much used as a-c ammeters and voltmeters in a wide variety of ranges and sizes. Electrical characteristics are given in Table 4. The range of the ammeters is from 20 ma to 500 amp. The upper limit is ten times that of dynamometer-type meters, because the current coil is fixed. Currents up to 5,000 amp are measured by the use of current transformers. The range of the voltmeters is from 1 to 750 volts. The resistances are such as to give from 3 to 200 ohms per volt, the values increasing with the voltage. Higher voltages are measured by the use of either multipliers or potential transformers. Moving-iron instruments used on d.c. may show gross errors due to residual magnetism in the vanes; the errors, up to 5 per cent, depend on previous peak values. They indicate true rms values on a.c., provided that on *peaked* wave forms the iron vanes have not saturated, and this is usually the case if the *peak* value of current or voltage is not over four times the full-scale rms value. Wave-form errors are discussed below.

25. Frequency Compensation. Moving-iron ammeters, if calibrated at 60 cps, usually show minor errors at higher frequencies, mainly due to eddy currents in the vanes and adjacent masses of metal. The magnitude of the error at 400 cps is generally small, however, and with the poorest designs of 90-deg deflection instruments will rarely be over 2 per cent. At 1,000 cps the best ammeters have a frequency error of not over 1 per cent. Long-scale (*i.e.*, 240 deg) ammeters may have gross errors (up to 50 per cent) at higher power frequencies and, if used outside their rated span, should be specifically checked at the frequency in question. The best moving-iron ammeters may be adjusted for use at a particular frequency to as high as 10 kc.

An uncompensated moving-iron voltmeter has a much larger error at the higher power frequencies. Basically a milliammeter in series with a calibrated resistance, the coil reactance and the meter impedance rise with frequency so that the indication drops rapidly with the increase in frequency and may be 10 to 50 per cent low at 1,000 cps. However, by shunting the resistance with a capacitor the coil current can be maintained substantially uniform at constant voltage and varying frequency. And, further, a slight overcompensation of the impedance will cancel the error due to eddy currents to give a reasonably flat voltage response up to several thousand cycles. The circuit is shown in Fig. 6.[1] An uncompensated voltmeter showing an error of 12 per cent at 1,000 cps can be compensated to have an error due to frequency of less than ¼ of 1 per cent from 60 to 1,100 cps. If greater coverage is desired the errors at intermediate points are greater so that, if the previously mentioned voltmeter were compensated at 1,500 cps, the maximum error would be 1 per cent at about 1,100 cps. Electrodynamometer voltmeters can also be compensated in a similar manner.

FIG. 6. Circuit diagram of compensated voltmeter.

In general the sensitivity of pointer-type indicating instruments using the moving-iron principle is from 0.1 to 1 watt full scale. Instruments using short vanes, usually of the arcuate type, take about 1 watt full scale. Instruments with long radial vanes are more sensitive with a minimum of 0.1 watt full scale but in general are more sensitive to external fields and must be well shielded and kept away from strong external fields. Moving-iron instruments are widely used on power circuits and are generally available in all sizes from the small 2-in. instruments up to the larger switchboard types.

HIGH-FREQUENCY CURRENT METERS

Because of the large reactance of any electromagnetic device at the higher frequencies, it is difficult to design such instruments for frequencies over 3,000 cps; while

[1] Miller, John H., Frequency Compensation of A-C Instruments, *Trans. AIEE*, **70** (6), 217, June, 1951.

occasionally used at 10 kc they may consume as much as 30 va for full-scale deflection. Above 10 kc some converting device is used, usually to produce a small amount of d.c. which is a function of the high-frequency current in question.

26. The Thermoammeter. If high-frequency current heats a short piece of fine platinum wire, and the temperature of the middle of the wire is measured with a thermocouple connected to a sensitive d-c millivoltmeter, the millivoltmeter scale can be calibrated in terms of the current in the heater. Such a simple assembly, however, does not compensate for variations in temperature of the terminals or for ambient-temperature variations.

The Weston thermal ammeter as developed by W. N. Goodwin, Jr., is as shown in Fig. 8. The heater is a wire or tube of platinum alloy of very short length whereby most of the heat is conducted to the terminals, thus wiping out largely the effect of convection currents of air. The temperature of the heated member may be represented as a parabola in its gradient from center to each terminal lug, and it is this temperature difference or gradient from the center of the heater to its end which is measured by the thermocouple. The couple proper consists of a pair of wires, usually of constantan and a
FIG. 7. Thermocouple meter.
FIG. 8. Compensated high-frequency thermocouple and heating element.

platinum alloy, permanently welded to the center of the heater at the junction end, with the effective cold ends soldered to a pair of copper strips which are thermally connected to, but electrically insulated from, the terminal lugs. Their heat capacity is such that the difference in temperature between the center of the heated member and the center of the two copper compensating strips is always the same as from the center of the heated member to the terminal lug, regardless of ambient-temperature changes or general rise in temperature of the surroundings due to heating of the lugs themselves or temperature rise due to the total heat generated. The thermoelectric voltage is, therefore, strictly proportional to the temperature difference between the center and ends of the heated member which in turn is proportional to the square of the current causing this temperature rise, and a d-c instrument connected to the couple may be calibrated in terms of this current.

27. Thermoelements. These may be designed to give suitable indication on instruments of commercial types from 200 ma up to whatever may be required. Solid round wires may be used for the heated member up to about 2 amp, but for higher currents and at the higher frequencies skin-effect phenomena cause the readings to be too high. For higher ranges, therefore, the heated member should preferably take the form of a thin-walled tube of such dimensions that the frequency error will not be excessive. For a frequency error of 1 per cent at 50 Mc, and for a platinum alloy tube having a resistivity of 170 ohms per cir mil-ft, the wall thickness is about 0.001 in.; at 100 Mc the readings will be about 5 per cent high. Since a 1-mil wall represents a practical minimum thickness of the heated tubular element, thermoammeters are not useful for even moderate accuracy at frequencies much higher than 150 Mc; as a practical matter above 150 Mc standing waves of even minor magnitude preclude accurate measurement of current values as such, and the intro-

duction of a line discontinuity by adding the thermoelement may also cause gross errors. Current measurements in the usual sense are, therefore, rarely made at above 150 Mc. It should be noted, however, that as long as the pointer of a thermoammeter does not deflect beyond full scale, no damage will occur to the thermoelement itself at any high frequency, and qualitative measurements may be made on frequencies much higher than 150 Mc.
FIG. 9. (*Above*) Standard scale using a conventional d-c movement. (*Below*) Linear expanded scale using specially shaped pole pieces.

While standard instruments have a square-law scale as the result of the I^2R production of heat, instruments are available in which the upper four-fifths of the scale is approximately linear through the use of special d-c indicating mechanisms having nonlinear air gaps whereby the d-c sensitivity is progressively lower as the pointer moves up the scale. By a proper combination of such specially shaped pole pieces a nearly linear scale may be produced. (See Fig. 9.)

Instruments having the linear expanded scale are useful in small broadcast transmitters licensed for a lower power at night than during the day; sufficiently accurate readings of the high and low values of antenna current may be had on the same instrument to be satisfactory, and instruments of this type are listed as complying with FCC rule No. 143.

For low ranges so-called *bridge-type* thermoelements are used, as shown in Fig. 10, whereby a number of couples are arranged in series-parallel to give a higher thermal emf. The impedance of these couples is higher than for a single couple, and for the common current-squared galvanometer the effective resistance is 4.5 ohms. The indicating instrument for the standard single-unit thermoelement has a sensitivity of 12 mv and a resistance of about 5 ohms.

FIG. 10. Galvanometer or bridge-type couple.

28. Vacuum Thermoelements. For still higher sensitivities the assembly may be placed *in vacuo*. Such thermoelements show no increase in sensitivity until the vacuum is better than 0.01 mm. of mercury; as the vacuum is increased, the sensitivity of the low ranges with very fine heaters increases markedly since there is no cooling by convection currents. Characteristics of a line of vacuum thermoelements are listed in Table 5, as made by Weston, and are typical. Metallic heaters are used on the higher ranges, with a carbon filament for the heater of the 1.5- and 2.0-ma ratings.

Both contact and insulated types are made and listed. In general the contact type is more efficient, and the output resistance is lower. In the insulated type a tiny ceramic bead connects the couple junction and the heater, thus insulating the two while allowing heat to flow from the heater to the junction. The equivalent capacitance across the bead is less than 1 $\mu\mu$f. Because less heat flows across the bead, the couple wires must be smaller and the output resistance is higher as listed.

Vacuum thermoelements are quite rapid in response. If a given current is suddenly sent through the heater and maintained, the output millivolts will increase in a manner departing only slightly from an exponential curve, and we may thus define the "time constant" as the time for the output to rise to 63 per cent of its steady-state value.[1] For all except the carbon-filament ranges, the time constant so defined

is between 0.1 and 0.2 sec for the contact types (including higher ranges in air as previously described); the insulated types will run 0.2 to 0.3 sec because of the time lag of the bead.

These thermoelements are to be used with 10-ohm, 200-μa instruments, and are used either external to the instrument or self-contained in the instrument case. In some instances they are associated directly with the coaxial line to simplify the r-f system, with leads to the instrument. Frequency errors will vary with range; up to 150 Mc such errors are usually under a few per cent. Care must be taken to avoid r-f currents in the couple which will heat the junction independently of the heater current; chokes in the instrument leads and capacitance to ground may be required to maintain this condition.

FIG. 11. Physical dimensions of thermoelements listed in Table 5.

29. Thermoammeters in general are calibrated on commercial frequency a.c.; if used on d.c., the mean of reversed readings should be taken to make certain that any d-c drop in the heater picked up by the couple is canceled out. They may be obtained with a separate thermoelement for use in indicating at a distance as where a thermoelement is placed in the antenna of a transmitting station and the leads brought back to an instrument in the transmitting building. The thermoelement should be placed in the h-f circuit at a point close to ground potential to reduce circulating r-f currents in the leads to the instrument. If this cannot be done, the thermoelement,

of low range, around ½ amp, is connected to a loop of wire that is inductively coupled to a loop in the main antenna circuit. The thermoelement circuit may then be grounded. The instrument is scaled to read the total antenna current, and the final calibration is made by adjusting the inductive coupling between the two loops until the remote-reading instrument indicates the same value as an instrument placed directly in the antenna itself. Note that FCC rules require an instrument in the main antenna circuit which may be used for this purpose but which under normal operating conditions is kept short-circuited to prevent damage due to lightning. The switch is opened when the instrument is read, and the remote indicator, usually located on the transmitter panel, is used for normal operation.

The ratio of the power available to operate the indicating meter to that put into the heater is about 1 to 2,000 for the most efficient couples; hence a very sensitive d-c instrument is required for low r-f energies.

30. Thermocouple voltmeters are constructed by using one of the more sensitive couples with sufficient series resistance to give the desired voltage range. Their range is from 0.3 to 150 volts with resistances of 125 ohms per volt above 1 volt, and 500 ohms per volt above 10 volts, if desired. Their frequency range is determined by that of the series resistance. The small resistance spools which must be used in meters with self-contained resistors change in resistance rapidly with frequency so that their frequency limit is 3 kc. Frequencies of 1 Mc may be attained with an error of 1 per cent with special h-f resistors.

Since the emf produced by the thermocouple is proportional to the power input and hence to the square of the current, this meter will read correctly on both d.c. and a.c. and may, therefore, be used as a transfer instrument. It is necessary, however, to take the average of the readings for both directions when using d.c.

RECTIFIER METERS

31. Rectifier Meters. The full-wave preferred type of rectifier meter includes a bridge rectifier with four rectifier disks in circuit with a d-c meter as shown in Fig. 12; the figure also shows a series resistance R making this a rectifier voltmeter. With perfect rectifiers having zero forward resistance and infinite back resistance, if 1.0 ma a.c. is passed into this network and is measured with an rms or effective-value instrument, the meter receives a pulsating d.c. having a value of 0.9 ma since the d-c meter indicates the average value. The reciprocal of this ratio, 1.11, is the *form factor* of a sine wave, equal to $\pi/(2\sqrt{2})$, and this represents the ratio of the rms value of the sine-wave input into an ideal bridge rectifier, to the average value of its d-c output.
FIG. 12. Copper-oxide rectifier bridge.

Rectifier meters as milliammeters, or with appropriate series resistance as voltmeters, are usually calibrated on sine-wave a.c., or voltage, in terms of the rms value. On d.c. or on square-wave a.c. they will therefore read 11 per cent high. And on other wave shapes they will read in terms of the form factor of that wave shape.

32. Rectifiers Used in Rectifier Meters. In spite of the availability of excellent silicon and germanium rectifiers, copper-oxide rectifiers are the preferred type used in most rectifier meters. Since the drop across the instrument mechanism itself is of the order of a few hundred millivolts and the resistance of the instrument moving coil is low, the relatively low forward resistance and, more particularly, the low voltage drop across copper oxide gives the best impedance match. This factor is particularly important in rectifier milliammeters since a milliammeter is placed in series with a circuit in which, presumably, it will have little or no effect and maintaining a low resistance is quite important. Likewise for measuring low a-c voltages a low resistance of the rectifier meter is desirable so that the maximum amount of series resistance may be used to swamp out to the greatest degree the effect of temperature on the

measuring system. On the other hand, for rectifier-type voltmeters having ranges of over 50 volts, or for rectifier-type milliammeters to be used in high-impedance circuits, the silicon diode becomes the preferred rectifier. Thus, while the standard rectifier meters continue to use copper-oxide rectifiers, rectifier meters may be obtained from most makers on special order including silicon diodes where the added accuracy and perfection of rectification are worth the considerable extra expense involved.

Other rectifying systems such as those using selenium or copper-sulfide rectifiers are not used because of the high drop at low currents.
FIG. 13. Current-efficiency characteristic.
FIG. 14. Impedance characteristic of 20-ma rectifier instrument at 60 cycles.

33. Commercial Rectifier Instruments. These usually contain the full-wave rectifier described above, and this applies as well to power-level indicators and VU meters discussed later. However, many multiple-range instruments for radio servicing use a half bridge or some modification of a half-wave system as an economy; the lower efficiency can usually be tolerated since practice in these assemblies generally dictates a d-c voltmeter sensitivity of 50 μa full scale, to give d-c voltage ranges at 20,000 ohms per volt, whereas the a-c ranges are at 1,000 ohms per volt.

Because there is a small back current in the copper-oxide rectifier the current efficiency, defined as the ratio of the average d-c output to the rms a-c input, is less than the 90 per cent theoretical maximum efficiency and Fig. 13 shows the current efficiency of a typical copper-oxide rectifier for instrument use. However, since

rectifier meters are adjusted and calibrated as an assembly, this slightly lower efficiency is not material and is calibrated into the meter as a whole.

In general the impedance of the rectifier rises with lower currents, and Fig. 14 shows typical values of effective impedance for a 20-ma rectifier instrument with current.

Temperature variations have considerable effect on both the impedance and accuracy of rectifier instruments. Figure 15 shows temperature-voltage variations for a specific group of milliammeters from which impedance can be determined. Figure 16 shows temperature-efficiency relations of this group at various current values. The point must be stressed, however, that the curvature of these characteristics varies with the several parameters of rectifier-disk size, current density, processing time, and the resistance of the instrument, and it is quite possible to modify these curves materially for special requirements. Standard instruments, by the same token,
FIG. 15. Effect of ambient temperature on the voltage drop across a rectifier instrument at various currents.
FIG. 16. Ambient-temperature efficiency relation for several typical rectifier-type milliammeters.

can hardly be represented by any particular group of curves. Rectifier instruments have been materially improved in recent years as to the flattening of the curves, and design possibilities have broadened to the point where materially improved instruments can be made for particular requirements.

Higher temperatures adversely affect the rectifying film, and rectifier instruments may become erratic at temperatures in excess of 45°C. High-temperature locations should be avoided; where the instrument becomes unduly warm, instruments with external rectifiers are sometimes used with the rectifier placed in a relatively cool location.

Frequency errors are the result of capacitance between disks. Since the disk resistance is lower at higher currents and since capacitance is a function of rectifier size, the smallest rectifier is preferred for good frequency characteristics. This in turn means a high current density with which good accuracy is obtainable somewhat above audio frequencies. With low-current density, errors may be as large as 1 per cent per 1,000 cycles.

In general, low-range voltmeters are more subject to temperature and frequency errors than high-range voltmeters. Low-range voltmeters have scales which are compressed at the lower end owing to variations of impedance with current. High-range voltmeters and milliammeters have nearly uniform scale distribution.

Table 6 gives approximate constants of commercial rectifier instruments.

Table 6. Milliammeters and Microammeters

Full Scale, Ma	Approximate 60-cycle Impedance at Full Scale*
15	100
10	130
5	190
2	370
1	600
0.5	1,140
0.2	1,950
0.1	4,200
0.05	6,300
0.02	10,000

* Individual copper-oxide rectifiers vary considerably from the average in characteristics. Impedance values given may vary ±15 per cent, and efficiency values vary ±3 per cent for the product of *one* manufacturer. Much greater variations may be expected between the products of *different* manufacturers.

34. Power-level Instruments. For monitoring power level in voice-frequency circuits the instruments are usually rectifier-type voltmeters with scales calibrated to read power on the basis of a fixed resistance load. Indications are in decibels above or below a specified zero power level; alternatively they may be in VU, amounting to decibels above or below 1 mw, and as defined in the section on the VU meter. The zero level for power-level instruments marked in decibels has been considered as 6 mw in the older versions but currently 1 mw is becoming the standard and instruments marked in decibels and using this level frequently carry the caption DBM.

The older instruments with a full-scale value of 6 db above a zero level of 6 mw in 500 or 600 ohms carry a scale as shown in Fig. 17. The instrument is basically a rectifier-type voltmeter with a resistance, measured at full scale, of 5,000 ohms and adjusted to 3.79 volts full scale and 1.90 volts at zero level. The value of 5,000 ohms was selected to minimize the loss in line energy due to the addition of the power-level indicator and also to avoid harmonics to the line due to the nonlinear shunt resistance of the instrument rectifier network.
FIG. 17. Scale of typical power-level meter.

35. The VU Meter. The VU meter, which is currently the common denominator used in monitoring voice-frequency circuits, was developed in order that a standard-level indicator might be made available. It is rather completely described by Chinn, Gannett, and Morris in their classic paper.[1] The original work envisioned the instrument as always to be used across a 600-ohm source feeding a 600-ohm load. However, with the use of 150-ohm lines in more recent practice, particularly in television, an alternative arrangement for use on 150-ohm lines has been developed. And in recognition of the fact that the basic instrument may be used in conjunction with lines of any resistance, the latest edition of the standard is quite general and considers the use of the meter across lines of any stated impedance.

More specifically this standard is referred to as "IRE Standard on American Recommended Practice for Volume Measurements of Electrical Speech and Program Waves 1953" and was printed in the *Proc. IRE*, May, 1954. It is also considered as an American Standard and carries the reference C16.5-1954.

Two instrument scales have been standardized, as shown in Fig. 18. The *A scale* emphasizes the VU markings and has an inconspicuous voltage scale. The *type B scale* emphasizes the per cent voltage and has a relatively inconspicuous VU scale. This latter scale is largely used in broadcast monitoring since the voltage scale indi-

[1] Chinn, Gannett, and Morris, *Proc. IRE*, January, 1940; A New Standard Volume Indicator and Reference Level, *Bell System Tech. J.*, January, 1940.

cates in a rather direct fashion the per cent utilization of the facilities. The scales are printed on buff paper to reduce eyestrain; the narrow arc and the figures above it are in black with the heavy arc to the right, the markings above it as well as the markings below the arc in red.

The instrument mechanism, which is identical for both scales, has very definite ballistic characteristics which may be completely defined by the fact that, if a voice-frequency voltage of such amplitude as to give a steady reading of 100 on the voltage scale is suddenly applied, the pointer should reach 99 on this scale in 0.3 sec and should then overswing the 100 point by between 1 and 1.5 per cent.
Fig. 18. (*Above*) A scale for VU meter. (*Below*) B scale for VU meter.

Since a voice-frequency channel contains many components of different frequencies, the dynamic standards listed above are a very necessary part of the specification for the instrument. The instrument is standardized on sine-wave voltage at 1,000 cps in terms of the rms value of that voltage and is adjusted to read to the 100 mark on the voltage scale with 1.22 volts applied to the standard instrument as furnished plus a 3,600-ohm external series resistance, this representing 4 db above 1 mw in 600 ohms.

With such an instrument, the readings obtained from it when voice-frequency currents are applied may then be stated as so many VU, taking into account that 4 VU must be added to the scale reading plus the number of VU lost in the attenuator placed in the network.
Fig. 19. Network for use with VU meter and 600-ohm line.

36. Applying the VU Meter. The VU meter is connected across a 600-ohm line feeding a 600-ohm load as shown in Fig. 19. The fundamental total resistance of the instrument is 7,500 ohms. To this is added 300 ohms representing a 600-ohm source and load in parallel, making a total of 7,800 ohms. To simplify the use of an attenuator, this is split in the center to give 3,900 ohms each siae, which will allow a simple T-pad attenuator to be inserted at this point. The instrument proper, therefore, has an internal resistance of 3,900 ohms and must be used with the separate 3,600-ohm resistor. Since the normal instrument level is +4 VU, the attenuator dial is marked 4 VU at zero attenuation, and for other true attenuation values 4 VU are added. Table 7 shows values for such attenuators.

For use on 150-ohm lines it was found impractical to change the potential and current relations in the VU meter because of the finite resistance of the self-contained rectifier, and it would also have required another type of basic instrument. Consequently another approach was investigated and it was found that the standard meter could be coupled to the 150-ohm line through an appropriate transformer which, effectively, lowered the meter impedance by a factor of 4 while maintaining

the appropriate power ratios. Figure 20 shows the recommended connections of the standard VU meter to a 150-ohm line. The transformer is a low-loss toroidal type
FIG. 20. Network for VU meter for use on a 150-ohm line.

such as the General Radio Type 941A, the transformer itself having its terminals connected as shown in Fig. 21. The transformer is used directly with switches *T* closed and up to any level for which the transformer is suitable. Switch *S* may be opened for a fully insulated system or omitted entirely and this circuit may be closed if a grounded system is deemed satisfactory.

FIG. 21. Terminal-connection diagram for coupling transformer associated with VU meter on a 150-ohm line.

However, since any transformer has some power limitation, and since a 12-db pad can be arranged to serve as a match between the line and load, Fig. 20 shows an arrangement where the transformer is switched out of the circuit and a fixed pad switched in at the 12-db or −16 VU point; the two line switches are transferred to *P*, and switch *S* must be closed if left open previously. Reference is made to Table 8, giving the attenuator values for this network, and it will be noted that at the 12-db position on the attenuator the transformer is taken out of the circuit and a fixed 12-db loss network is added, after which the instrument is directly connected. It is convenient to associate these transfer switches with the 12-db position on the attenuator and it might be noted that it is possible to use the resistor elements for the first 11 steps over again for the higher steps shown in the tabulation of resistance values.

Any other type of attenuator, such as a balanced H, may be used, with the matching transformer ahead of the attenuator throughout, or transferred to a fixed pad at the higher levels as may best suit the requirement of any particular level and circuit.

The VU meter is available commercially from several manufacturers and because of its moderate speed of action it is quite readable. It is considered today as the standard monitoring instrument and is available in several sizes, the one in most common use being approximately 4 in. square and available either with or without internal illumination.

The VU meter is also finding favor in applications other than across a-f lines, for example, as a monitoring instrument in sound recording on film, tape, or disk. It has largely superseded the previously used db meters having other dynamic characteristics, zero levels, etc. There is still some application, however, for the high-speed variety of db meter in the cutting of records where instantaneous indication and control of top level are desirable to prevent overcutting.

Table 9 is a useful tabulation of power levels, ratios, and voltages, all in terms of a zero level of 1 mw, with the last column—voltage—based on 1 mw in 600 ohms as the zero level. When interpreted on a VU meter as described, the values of db above and below this level also represent VU.

MEASUREMENTS OF PULSATING CURRENTS AND POTENTIALS

In making measurements of current and voltage which are neither true a.c. nor d.c., care must be taken to make the measurement with the correct type of instrument in order that a measurement be had of the actual value required.

37. Rectified-current Measurements. Rectified current, which may or may not be filtered, should in general be measured with a moving-coil permanent-magnet type of d-c instrument. This gives the average value. It is the value of current or voltage of interest when charging a battery and in general is the value of interest in vacuum-tube technique. Iron-vane and electrodynamometer instruments indicate the rms value which is used for determining the heating effect.

38. Measuring Pulsed Currents. Direct-current ammeters and milliammeters used to measure the average value of pulsed currents indicate the *average value* of the current but are heated by the *rms value*. For example, a 100-amp d-c pulse, 1 millisec long, repeated every 100 millisec, has an average value of 1 amp and will so indicate on a 1-amp d-c instrument. But, whereas a continuous current of 1 amp will cause a loss of 0.05 watt in a typical 1-amp instrument, the pulsed current in the example, giving the same reading, will cause a loss 100 times as great, or 5 watts; this is effectively the same loss as 10 amp of continuous current or a current overload of 10 times. This may overheat the instrument and cause permanent damage; in extreme cases instruments in applications of this kind have been burned out when reading below full scale.

Thus, for pulsed-current applications where the pulse repetition time is more than ten times the pulse length, special precautions should be taken. Oversize external shunts, heavy wire actuating coils, and other expedients usually allow an appropriate instrument design for any given set of conditions. The point must be stressed that standard instruments may be damaged in such service and the instrument manufacturer should be called on for an appropriate special design to meet the stated conditions.

To measure the a-c component of voltage, a capacitor may be placed in series with an a-c voltmeter of suitable range; the d-c component is blocked and the a-c value only is measured. The impedance of the capacitor at the frequency used (120 cycles for a full-wave rectifier system) should not be greater than 10 per cent of the instrument resistance; the impedances being in quadrature, the resulting error will be under 1 per cent. This is the simplest method of measuring hum in a rectified plate supply. Because of its high resistance, the rectifier voltmeter described previously is most satisfactory for this purpose.

Peak voltages and currents are best measured through the use of a vacuum-tube voltmeter with a large capacitance shunted by an extremely high-resistance d-c voltmeter. A cathode-ray oscillograph is also useful in such studies.

VOLTAGE-MEASURING INSTRUMENTS

39. Use of Current Meters to Indicate Voltage. All current-measuring instruments having a sensitivity in milliamperes may, with the addition of suitable series resistance, be used to indicate potential. The current drain of the instrument must be sufficiently low to abstract negligible energy from the circuit, as otherwise corrections must be made. With modern instruments of high sensitivity this requirement can usually be met.

Direct measurements of voltage are obtainable through electrostatic means, but the instruments are of limited utility because of their low torque and because the minimum ranges are rarely under several hundred volts. They are essentially instruments for the research laboratory.
FIG. 22. Suspended-vane meter.

Electrostatic voltmeters depend on the attractive force which exists between two conducting plates between which a difference of potential exists. In their simplest form, the force of attraction between a stationary and a movable disk is balanced by a calibrated spring. The *Kelvin absolute electrometer* is constructed in this manner. The force of attraction is proportional to the square of the difference of potential between the plates. Such meters give the same indication on steady and alternating voltages and have neither wave-form nor frequency error.

One type of construction, used in suspended-vane meters, is shown in Fig. 22. The stationary plates are sections of two concentric cylinders, into which the cylindrical rotor turns. With the opposite poles of a magnet placed outside the stator plates, satisfactory damping is obtained from the currents induced in the loop. This type of construction is that used in the *Ayrton-Mather electrostatic voltmeter* built by the Cambridge Instrument Company.

Electrostatic voltmeters are very useful because of their high resistance and low power consumption at low frequencies. They cannot be used on high voltage at frequencies much above 1 Mc, because of the rapid increase of the power loss in the necessary insulation. This loss increases directly as the first power of the frequency and the square of the voltage. A hard-rubber insulator with a power factor of 0.004 and capacitance of 10 $\mu\mu$f will have, at a frequency of 10 Mc and voltage of 2.5 kv, a charging current of 1.5 amp and a power loss of 15 watts, both of which values are excessive.

MEASUREMENT OF RESISTANCE, IMPEDANCE, FREQUENCY

40. Resistance. While bridge measurements of resistance give greatest accuracy, direct-reading instruments are much used because there is no requirement for the manipulation of the controls, and they are widely used in production testing of resistance units as well as in general laboratory practice where the highest accuracy is not essential.

41. Ohmmeter. The simplest direct-reading ohmmeter consists of a milliammeter, a dry-cell battery, and a series resistance as shown in Fig. 23. With the terminals short-circuited, *i.e.*, $R = 0$, the shunt rheostat B is adjusted until the milliammeter I indicates full scale. When a resistance is connected across the terminals the reading of the instrument in terms of full-scale current can be expressed as
FIG. 23. Direct-reading ohmmeter circuit.

$$I \text{ (per cent)} = 100S/(S + R)$$

In this equation S is the resistance of the entire metering circuit to the terminals including both the series resistance marked S, any minor resistance in the battery proper, and the resistance of the shunted meter. Adjusting the meter shunt to take

care of variations in battery potential is preferred to the use of a variable series resistance since the shunt adjustment affects the circuit resistance to a much lesser degree. Further, to cover a battery-voltage variation of from 1.55 down to 1 volt per cell usually requires that the resistance B vary from 1 to 3.5 times the meter resistance; still better coverage is by making the B only the variable part or 2.5 times the meter resistance in series with a fixed resistance equal to the meter resistance. Thus, for a typical 1-ma meter having a resistance of 100 ohms the shunt would consist of a fixed resistance of 100 ohms and a variable resistance of 250 ohms.
Fig. 24. Circuit for five-range series ohmmeter, with basic scale 0 to 500 ohms, 25 ohms at center.

With this type of ohmmeter the center-scale value is equal to the resistance of the shunted meter plus the series resistance. The total usable range may be taken as from 0 to 20 times the meter resistance. In this example, for measuring low resistance
Fig. 25. Scale for ohmmeter of Fig. 24 with supplementary lower scale in volts and milliamperes.

values with a single dry cell, the shunted-meter resistance is approximately 53 ohms, the series resistance should then be 747 ohms, and the equivalent network resistance and the value for center scale would be 800 ohms.

The circuit of Fig. 24 shows a typical five-range ohmmeter obtained by switching in different shunt and series resistors, with a 15-volt battery of small current capacity for the highest range. The fixed shunt resistor is 4 times the meter resistances, with the variable unit 6 times the meter resistance. This means a minimum battery voltage of 1.375 volts per cell, but this higher cutoff point allows better use of the available meter sensitivity. The resulting scale for the lowest range of the diagram is shown in the upper scale of Fig. 25; multipliers are applied to this ohm scale for the other ranges as indicated. The evenly divided scales below the ohm scale are for voltage ranges of a typical volt-ohmmeter, obtained by switching from the ohmmeter network to an appropriate network of series resistors.

Fig. 26. Ohmmeter of Evershed and Vignole.

The upper limit of resistance measurements by this means depends upon the instrument sensitivity and battery voltage; a 50-μa instrument at 15 volts gives an excellent deflection on several megohms. The lower limit, since a minimum battery voltage of 1.5 volts must be used, is dependent only on the current capacity of the battery and the resistance of the leads. In general, for accurate work, the effective battery resistance must be calculated into the circuit as a part of the total series resistance.

The readings of an ohmmeter may be made independent of the applied voltage by dispensing with the controlling springs and obtaining the controlling torque from

a separate coil connected across the supply voltage. Figure 26 shows the circuit used by Evershed and Vignole in their ohmmeters of this type.

This construction was first used by Evershed for an ohmmeter designed to measure resistances up to 100 megohms. The source of voltage was a self-contained high-voltage magneto generator, giving voltages up to 500 volts. It was called a *Megger*. The same principle has now been applied to ohmmeters of lower range using battery voltages. The resistance range extends from 1 ohm to 5,000 megohms.

The upper resistance limit is greatly increased by replacing the microammeter with a vacuum-tube voltmeter connected across the fixed resistance, which may then have a maximum value of 10^9 ohms. The range will be 20,000 megohms.

The range is still further increased by using, instead of a VTVM, a degenerative d-c amplifier with a sensitivity of 0.1 volt for full-scale deflection of the indicating milliammeter. For a fixed resistance of 1,000 megohms, the current corresponding to this full-scale deflection is 100 $\mu\mu$a and 1 per cent of this, or 1 $\mu\mu$a, can be detected. At 100 volts the corresponding resistance values are 1 and 100×10^{12} ohms, since at all times the fixed resistance is negligible compared to the unknown resistance. It follows then that the voltage across the unknown resistor is essentially constant. The power supply is usually tube-regulated and is provided with a protecting resistor to limit the current on a short circuit to a safe value. One decade of resistance covers 90 per cent of the scale length, so that it is necessary to provide at least two fixed resistances per decade in order to keep the fractional accuracy of reading reasonably constant.

42. Measurement of Impedance. When the voltmeter-ammeter method is used with a source of alternating voltage, the ratio of voltage to current gives the impedance of the load

$$Z = E/I \qquad (2)$$

With the usual a-c instruments the corrections for the instruments are larger than for d-c instruments and more difficult to make because of their reactance. The high-resistance rectifier voltmeter and vacuum-tube voltmeter eliminate this difficulty.

The separation of impedance into its components requires the use of a wattmeter. The connections of Fig. 27*a* are usually used when no correction for instrument errors is to be made, while those of Fig. 27*b* allow the correction to be made quite easily. For this distinction the current coil of the wattmeter is grouped with the ammeter and its potential coil with the voltmeter. As before, the impedance of the load is given by Eq. (2). Its power factor is the ratio of the wattmeter readings to the product of voltage and current.
FIG. 27. Measurement of impedance.

$$\text{Pf} = \cos\theta = W/EI \qquad (3)$$

where θ is the phase angle between voltage and current. The resistance of the load is

$$R = W/I^2 \qquad (4)$$

and the reactance

$$X = \sqrt{W^2 - R^2} \qquad (5)$$

With the knowledge as to whether the load is inductive or capacitive, its inductance or capacitance may be calculated from

$$X = \omega L = -1/\omega C \qquad (6)$$

where $\omega = 2\pi f$.

43. Measurement of Capacitance. Since the power factor of the usual capacitor is small, its reactance is approximately equal to its impedance. This may be measured directly by the voltmeter-ammeter method and the capacitance calculated from Eq.

(6). At a given voltage and frequency, a single ammeter reading is sufficient, and the ammeter may be calibrated to read capacitance directly.

Capacitance may also be measured on a single indicating meter whose readings are independent of the applied voltage. The moving element consists of two coils set at
FIG. 28. High-frequency microfarad meter.

right angles to each other. There are no controlling springs. The connections used in the h-f Weston microfarad meter are shown in Fig. 28.

CHAPTER 14

ALTERNATING-CURRENT MEASUREMENTS

BY B. J. DASHER[1] AND JOHN TAYLOR[1]

VACUUM-TUBE VOLTMETERS

At frequencies above a few hundred cycles dynamometer and iron-vane ammeters become impractical, partly because at higher frequencies greater sensitivity is required (because impedances are likely to be higher) and partly because stray capacitance and other second-order effects make it difficult to maintain reasonable accuracy. At these higher frequencies thermocouples offer the only practical means for measuring current. They are satisfactory up to frequencies of the order of 100 Mc. Above this range indirect methods must be used. For example, current can be computed from measurements of voltage and impedance.

Fortunately, it is comparatively easy to measure voltage at frequencies up to several hundred megacycles. Vacuum-tube voltmeters are most often used for this application. Rectifiers in conjunction with sensitive milliammeters are also frequently used.

1. D-c Vacuum-tube Voltmeters (VTVM). A simple form of vacuum-tube voltmeter consists of a triode amplifier with a milliammeter in the plate circuit as shown in Fig. 1. If the supply voltages are selected so that the operating point for the tube is in the "linear region" the average plate current is very nearly proportional to the input voltage E_{in}. Since the plate current is not zero when E_{in} is zero, it is desirable to provide a "zero balance." A convenient way to do this is shown in Fig. 2.
FIG. 1. D-c vacuum-tube voltmeter.
FIG. 2. Vacuum-tube voltmeter with zero balance.

The battery E_m tends to send current through the meter in a direction opposite to that of the plate current. When the current in the meter is zero, the voltage drop in the balancing resistor just equals E_m. The sensitivity of the device is reduced by the addition of the zero balance because the incremental plate current must divide between the meter and the zero-balance circuit. However, the sensitivity of the meter can be increased to compensate for the reduction in inherent sensitivity.

The maximum sensitivity that can be obtained with this basic circuit is limited by the stability that can be achieved in balancing out the zero-signal plate current. Fluctuations caused by variations of heater voltage, plate-supply voltage, contact potentials, etc., must not be permitted to produce meter deflections comparable in magnitude to the deflections produced by the voltage to be measured.

Another basic VTVM circuit is shown in Fig. 3. In this arrangement, a voltmeter is used as the cathode resistor in a cathode follower.[1*] As in the previous circuit, a zero balance can be added to compensate for the zero-signal plate current. One such scheme is shown in Fig. 4. The input impedance of this circuit is extremely high—hundreds or thousands of megohms. Also, the degenerative feature inherently tends

[1] Georgia Institute of Technology.
* Superior numbers refer to references at the end of the chapter.

to stabilize the circuit. The range can be changed merely by changing the range of the voltmeter. In Fig. 3 the incremental current in the tube is given by

$$i_p = \frac{\mu E_{\text{in}}}{r_p + \mu R_m} = \frac{E_{\text{in}}}{R_m} \frac{1}{1 + r_p/\mu R_m} \tag{1}$$

in which μ is the amplification of the tube, r_p is the plate resistance of the tube, and R_m is the resistance of the voltmeter. Equation (1) may also be used for Fig. 4, provided R_m is replaced by the equivalent resistance of the meter and zero-balancing resistor is parallel.
FIG. 3. Degenerative or cathode-follower circuit.
FIG. 4. Degenerative circuit with zero balance.

Variations of the circuit in Fig. 4 are widely used in d-c voltmeters and also as basic parts of a-c voltmeters. The latter are discussed in Sec. 5.

2. Diode Voltmeters. A diode voltmeter is a form of rectifier instrument. However, the term "rectifier" usually is applied to instruments employing copper-oxide rectifiers whereas the term "diode" usually implies the use of vacuum diodes as rectifiers. In addition, diode voltmeters are generally designed to give readings proportional to the peak value of an a-c voltage, but rectifier instruments give readings proportional to the full-wave average values. Because of the characteristics of copper-oxide rectifiers, rectifier instruments are restricted to use at audio frequencies, but diode voltmeters may be used at frequencies of the order of several hundred megacycles. Semiconductor diodes are sometimes used instead of vacuum diodes. The indicating instrument is invariably a D'Arsonval-type d-c meter.
FIG. 5. (a) Basic diode circuit; (b) wave forms.

The basic circuit of a diode voltmeter is shown in Fig. 5a. The corresponding current and voltage wave forms are shown in Fig. 5b. If the time constant RC is large compared with the period of the a-c voltage to be measured, the voltage across the capacitor and, thus, across the resistance will be essentially a d-c voltage equal to the positive peak of the input voltage. Note that the diode is in series with the input voltage. Hence, the source must provide a d-c path; otherwise no current can flow through the diode. If the input voltage contains a d-c component, the meter current indicates the net peak positive voltage.

A second circuit, sometimes called a shunt circuit, is shown in Fig. 6a and the corresponding wave forms are shown in Fig. 6b. Compared with the series circuit, the shunt circuit has the advantage that the measured source need not provide a d-c path. Also, it is frequently advantageous to have the cathode of the diode at ground potential. The average voltage across the diode and, thus, across the meter resistance is nearly equal to the positive peak value of the input voltage, exclusive of any d-c component, since the capacitor C prevents any direct current from flowing in the meter circuit. The full input voltage is impressed on the meter-resistance circuit in addition to the d-c voltage.

In both the above circuits the emf induced by the emission velocity of the electrons from the cathode of the diode will produce a small deflection of the meter when the input voltage is zero. This emf is normally about 1 volt. This emf may be balanced out by means of a zero-balance circuit similar to those already described. Sometimes a mechanical adjustment is provided on the meter movement for zero balance.
FIG. 6. (*a*) Shunt circuit; (*b*) wave forms.

For small voltages (10 volts and less) the response of the diode voltmeter is noticeably nonlinear and special scales must be provided for the low-voltage range.

As may be seen from Fig. 6*b*, the peak voltage across the resistor is the peak-to-peak voltage of the input wave. Thus, if the resistance-meter combination is replaced by the peak reading meter (Fig. 5*a*), the so-called *voltage-doubling* circuit of Fig. 7 is obtained. In this circuit the first diode has been reversed so as to give a positive direction for the d-c current. In these discussions the voltage drop in the diode during conduction has been neglected. Although this voltage drop causes the voltage across the resistance to be slightly less than otherwise, the current is almost directly proportional to the input voltage. Thus, the meter can be calibrated to indicate the actual voltage.
FIG. 7. Voltage-doubling circuit.

3. Input Impedance of Diode Voltmeter. It is always wise to be aware of the finite input impedance of voltmeters, especially at high frequencies. The presence of the meter may appreciably affect the circuit under measurement. The input impedance is represented with good accuracy as a capacitance in parallel with a resistance. The capacitance can be reduced to 1 or 2 $\mu\mu$f with careful design, but it is usually much larger. When the voltage being measured is sinusoidal or nearly so, the input resistance of the instrument can be evaluated in terms of the power dissipated in the resistor. In the circuit of Fig. 5,

$$R_{\text{in}} \approx R/2 \tag{2}$$

In Fig. 6,

$$R_{\text{in}} \approx R/3 \tag{3}$$

and in Fig. 7,

$$R_{\text{in}} \approx R/8 \tag{4}$$

The fundamental component of the diode current leads the input voltage slightly. The angle is small and decreases with increasing frequency. When the voltage is not sinusoidal the power input is approximately $(E_{\text{peak}})^2/R$ and this is usually a more significant quantity than the equivalent input resistance since the value of the resistance depends on how it is defined. At frequencies high enough so that the transit time for the electrons in the diode is an appreciable part of a period, the input resistance is less than given by the appropriate equation (2), (3), or (4) because of the energy absorbed by the electrons. A careful analysis of this effect can be made only by considering specific circuits, tubes, etc. Transit-time effects also introduce additional errors.[2]

4. Wave-form Considerations. Vacuum-tube voltmeters are usually calibrated to indicate the rms value of a sinusoidal voltage. If the wave form is not sinusoidal the

indications must be interpreted with due attention to the wave shape. It is essential to know the circuit employed in the voltmeter. In the case of a square wave, the peak value is found by multiplying the meter reading by $\sqrt{2}$. For unsymmetrical waves useful generalizations are difficult to make. For example, in the case of very short pulses, the current pulse through the diode may be quite large, thus causing an excessive voltage drop in the diode. Under these circumstances, the meter reading will be appreciably less than the voltage peak. A full-wave circuit, such as Fig. 7, will give the correct value of the fundamental component of a wave containing only even harmonics as shown in Fig. 8. Such wave forms are typical of those produced by distortion in vacuum-tube amplifiers. On the other hand, if only odd harmonics are present, the wave form may be peaked as in Fig. 9. In this case, the reading will be appreciably higher than the fundamental component.
FIG. 8. Voltage wave containing only even harmonics.

These "errors" caused by nonsinusoidal wave forms are not so serious as they may at first appear. Thus, in the case of pulses, the peak amplitude may be the desired quantity. Similarly, it is usually satisfactory to measure the peak value of a saw tooth, square wave, or other wave of known shape. But if the wave-form characteristics are not known, the voltmeter readings may be quite meaningless. A cathode-ray oscilloscope is indispensable when dealing with nonsinusoidal waves. Its use as a voltmeter is discussed in Sec. 9.

FIG. 9. Voltage wave containing only odd harmonics.

5. Rectifier-amplifier Voltmeter. The sensitivity of the diode voltmeters described in Sec. 2 is limited by two factors: (1) for voltages below 10 volts the scales are nonlinear and dependent on individual tube characteristics; (2) full-scale current must be at least 50 μa unless fragile meter movements are used. Thus, the maximum practical sensitivity is of the order of 10,000 ohms per volt. To permit higher input impedances to be obtained and to permit very small voltages to be measured rectifier-amplifier combinations are commonly employed in commercial instruments. Two basic arrangements are in general use. In one, a diode rectifier is used followed by a d-c voltmeter. In this case, the voltage developed by the rectifier is used as the input to the d-c meter. Since no meter is needed in the diode circuit, the resistance can be made 10 to 100 times larger than would otherwise be possible.

In the second type of rectifier-amplifier instrument, the amplifier is an a-c amplifier and a diode voltmeter is connected to its output.
FIG. 10. Diode rectifier and d-c voltmeter.

Figure 10 shows a simplified schematic diagram of an instrument of the first type. R_1 and C_1 constitute a filter to prevent the a-c component of the diode voltage from appearing on the grid of the triode. In Fig. 11 a second diode-triode combination is added to provide a balance circuit which has much greater stability, since variations caused by supply-voltage variations, aging of tubes, and the like tend to cancel. The sensitivity of these circuits can be increased by the addition of a d-c amplifier stage but this does not overcome the nonlinear characteristics of the diode at low input voltages.

In the second type of circuit, the amplifiers are a-c amplifiers. In addition to being less critical as regards drift and aging of tubes, these circuits provide a comparatively

large voltage for the diode circuit. Various modifications of the circuits previously discussed may be used as the rectifier. In Fig. 12 the full-wave circuit shown yields a reading proportional to the full-wave average. Resistor R_2 prevents the capacitor from charging to the peak voltage.
FIG. 11. Balanced voltmeter circuit.
FIG. 12. Amplifier-rectifier vacuum-tube voltmeter.

The upper frequency limit of this circuit depends primarily on the band width of the amplifier. Practical designs give calibrations substantially independent of frequency up to 10 Mc. At higher frequencies, it is desirable to install the cathode follower in a probe so that the leads associated with the high-impedance portions of the circuit may be as short as possible. For the same reason, the diodes used in instruments of the type in Fig. 10 are frequently installed in a probe. Since these instruments do not require wide-band amplifiers, they are, in general, better suited for very high frequencies, but as pointed out above, they do not yield as high sensitivity as the second type. For frequencies above 100 Mc, the vacuum diodes may be replaced by semiconductor crystal diodes.

6. Square-law Voltmeters. Many variations of the circuits already described are possible,[2] but these circuits include the basic principles of most commercial instruments presently available. One other circuit is sometimes useful in the laboratory, although it is not generally available in a commercial instrument. This is the square-law voltmeter. The plate current of a triode operating near cutoff is nearly proportional to the square of the grid voltage. Hence, when an a-c voltage is applied to the grid, the average current, which is the d-c plate current, is proportional to the square of the rms grid voltage. Figure 13 shows a circuit that can be used as a square-law voltmeter. For large input voltages, this circuit operates essentially as a plate-circuit rectifier and gives approximately linear rectification and an indication proportional to the half-wave average of the input voltage.

FIG. 13. Square-law voltmeter with balancing tube.

7. Slide-back Voltmeters. The slide-back voltmeter is useful for measuring d-c voltages. It can be designed for greater sensitivity, higher input resistance, and

greater accuracy than other types of VTVM, but it has the disadvantage of being basically a comparison device and, consequently, not direct-reading.

The principle is illustrated in Fig. 14. This circuit is in reality an electronic potentiometer.[3] The resistor R_s is a calibrated "slide-wire" potentiometer, which, for best accuracy, should be of the Thomson-Varley type. If the total resistance of R_s is, say, 100,000 ohms then a current of 1 ma gives a total voltage of 100 volts across R_s. To operate the instrument, the push button Pb is depressed and R adjusted so that the tube current is exactly 1 ma. Then the push button is released and the potentiometer adjusted so that the current is again exactly 1 ma. Now the drop E_s across the potentiometer is exactly equal to the unknown voltage. By carefully selecting the operating point of the tube, the grid current may be reduced to a few parts in 10^9 or less to yield an extremely high input impedance. Voltages can be measured to four significant figures without difficulty. Of course, the slide wire must have corresponding precision, but the meter need be accurately calibrated at only one point.

FIG. 14. Slide-back vacuum-tube voltmeter.

When less precision is required, E_s may be measured with a voltmeter instead of a potentiometer.

8. Accuracy. The accuracy of vacuum-tube voltmeters is less than that of good-quality instruments for use at low frequencies. The reason for this is too involved to discuss here. However, accuracy attainable with commercial instruments is usually as good as 5 per cent and sometimes better. It is seldom better than 1 per cent, but accuracy better than this is seldom required. Frequency errors are negligible over a wide range. Therefore, a tube voltmeter can be calibrated at 60 cps by means of a standard instrument. In this way, higher accuracy can be obtained.

9. Cathode-ray Oscilloscope. A cathode-ray oscilloscope serves as a convenient voltmeter, especially at frequencies in the megacycle range. Some instruments have calibrated attenuators and self-contained calibrating circuits. Otherwise, the oscilloscope can be used as a comparison device, using a low-frequency instrument as a reference. It is necessary, of course, to have a knowledge of the frequency-response characteristics of the oscilloscope to obtain reasonable accuracy in this way.

10. Ground and Capacitance Considerations. When working at high frequencies it is not enough to have a well-constructed instrument. Failure to observe a few simple precautions can lead to errors more serious than those caused by the limitations of the meter.

One very important factor is the matter of ground connections. The ground terminal of the VTVM must always be connected to the ground terminal of the circuit under test. Otherwise, the capacitance between the two ground circuits will be added to the test circuit between its ground terminal and the point to which the meter ground is connected. Unless this part of the circuit has a very low impedance, spurious readings will result. This sometimes renders it impossible to measure the desired voltage. For example, the voltage across an interstage coupling capacitor usually cannot be measured directly. Instead, each voltage must be measured with respect to ground and the difference taken, with due attention to the phase difference in the case of alternating voltages.

Another factor that must always be remembered, especially in r-f circuits, is the influence of the meter on the circuit under test. At best, the VTVM adds a few micro-microfarads across the test points. This additional capacitance may alter the voltage. Resonant circuits, for example, should usually be retuned after the voltmeter is connected. The added capacitance may cause high-gain amplifiers to oscillate or it may otherwise alter their performance. As a general rule, the leads between the voltmeter and the test circuit should be as short as possible and when a probe is used the shielded cable should be kept away from high-potential portions of the test circuit. Excessively long leads may also produce resonance effects causing the voltage at the meter terminals to be different from the desired voltage.
FREQUENCY, WAVE FORM, AND PHASE

The fundamental frequency standard is the period of rotation of the earth. This period can be measured with great accuracy by astronomical techniques and serves as a reference to which all frequency measurements must ultimately be compared.

Standard frequency generators are classified as primary or secondary. A primary standard is one arranged for direct comparison with the earth's period at regular intervals. A secondary standard is one whose calibration is obtained by reference to a primary standard. The stability and accuracy of present frequency standards is excellent and it is relatively easy to measure frequency to an accuracy of a few parts in 10^8.

11. Frequency Standards. Present-day primary-standard frequency generators usually employ a carefully designed crystal-controlled oscillator to generate a frequency of 100 kc. This frequency is reduced to 1,000 cps by frequency dividers so designed that the 1,000-cycle frequency is used to drive an electric clock whose time is compared with the earth's period. Crystal oscillators are available that have a long-time frequency stability of a few parts in a hundred million. This represents approximately 0.001 sec in 1 day.

Secondary standards also employ carefully designed crystal-controlled oscillators. They differ from primary standards principally by the omission of the clock and associated means for comparing it with observatory time. Such a secondary standard can be expected to have a stability of a few parts in a million for long periods of time.

For laboratory standards, the National Bureau of Standards standard frequency transmissions are convenient. By means of a good communications receiver transmissions can be received in most parts of the United States 24 hr a day. They provide frequencies with an accuracy of better than 1 part in 50,000,000.

Time is also announced every minute from the Canadian station CHU in the 3- and 7-Mc bands.

Signals from commercial broadcast radio stations are usually maintained accurate to a few parts per million.

12. Frequency Meters. Two types of direct-reading frequency meters are presently available for use at radio frequencies.
FIG. 15. Counting-rate meter or frequency meter.

One type using direct indicating instruments in conjunction with electronic circuits covers a useful range from 3 cps full-scale to 60 kc full-scale. The electronic circuit generates pulses which are all of identical shape but which depend entirely for their frequency on the frequency of the applied voltage. The identical pulses are rectified and "counted" on a d-c instrument whose deflection is proportional to the number of pulses per second. The instrument is calibrated in terms of frequency in cycles per second. The maximum frequency range that can be covered with this type of instrument is limited only by the rate at which the pulses can be generated. The accuracy is similar to that of other direct-reading electronic instruments—about 1 per cent.

Figure 15 shows a simplified schematic diagram of the *counting-rate* type of frequency meter.[4] The input signal is amplified and applied to the input of a modified Eccles-Jordan circuit ("one-shot" multivibrator), which generates a standard pulse for each positive half

of an a-c voltage or each positive pulse input. The wave shape of this pulse is independent of its rate, which is the same as the input pulse rate. The positive pulses from the pulse generator are applied to the grid of a tube that has been biased beyond cutoff; plate current flows only while the positive pulses are applied. A filter or averaging circuit delivers a d-c voltage to a VTVM. Since the amplitude and duration of the pulses are constant and their separation equals the period of the input frequency, the average output voltage is proportional to the input frequency.

A second type of direct-reading frequency meter is literally a counting instrument.[5] A block diagram of a typical circuit is shown in Fig. 16.

The signal whose frequency is to be measured is led first to a pulse-forming circuit that delivers a very short pulse each time the sign of the input signal voltage changes from negative to positive. The pulses are fed to a gated amplifier and then to an electronic counting circuit. The time-base generator consists of a very stable, crystal-controlled oscillator and suitable frequency dividers. Suppose the oscillator frequency is 100 kc. Then five 10 to 1 frequency dividers provide an accurate 1 cps output. When the "count" switch is depressed, the time-base generator turns the gated amplifier "on" at the beginning of the next 1-cps period and turns it "off" at the beginning of the next successive period. Thus, the counter is permitted to count pulses for exactly 1 sec and the number of counts displayed is the average frequency (averaged over 1 sec) of the input signal.
Fig. 16. Block diagram of counting-type frequency meter.

The accuracy of the pulse-counting-type frequency meter is limited by the stability of the timing oscillator and by the fact that an integral number of counts must be registered. There is an inherent uncertainty of 1 count in the frequency indicated. Thus, if a frequency of 100 cps is to be measured to an accuracy of 1 part in 10^6 it is necessary to count for 1,000 sec. For the same accuracy the same number of counts will be required regardless of frequency, but for higher frequencies the counting time is, of course, less.

In commercial instruments the timing oscillator usually has an accuracy of a few parts per million, but provision can be made to use a separate oscillator of higher precision. The frequency range extends to 1 Mc and can be made higher through the use of a heterodyne oscillator (see Sec. 13).

Frequency Comparisons. A very common way to measure frequency is to compare the unknown frequency with a standard frequency. The heterodyne frequency meter operates on this principle. The basic components of a heterodyne frequency meter are a stable, tunable, calibrated oscillator, a detector and means to observe the output of the detector. Signal amplifiers and other elaborations may be provided according to the particular intended use of the instrument but the principle of operation remains the same. The unknown signal and oscillator output signal are fed into the detector (sometimes called the mixer). The frequency of the output from the detector equals the difference between the known and the unknown frequency. When the oscillator is adjusted so that this difference is zero, then its frequency equals that of the unknown frequency. The detector output may be observed by means of headphones, loudspeaker, cathode-ray oscilloscope, or even a voltmeter. When the detector output frequency has been adjusted to "zero beat," the frequency of the unknown signal is read from the calibrated oscillator.

The accuracy of the heterodyne frequency meter is limited by the accuracy and stability of the local oscillator. It is very difficult to construct a precision oscillator whose frequency can be varied over a wide range. Hence, the accuracy of heterodyne

meters is seldom better than a few parts in 10,000. In addition to the limitation set by the stability of the oscillator, there is the problem of providing a calibrated scale that can be read to more than three or four significant figures. The oscillator frequency itself may drift with aging of components and it may vary appreciably as a result of variations of power-supply voltages, ambient temperatures, and other such parameters. Consequently, heterodyne frequency meters are commonly provided with reference oscillators, in the form of carefully designed crystal oscillators. These can be used to check the calibration of the instrument so that adjustments can be made to compensate for drift. When such a crystal calibrator is included the calibration can be made dependable to about 1 part in 10,000 for indefinitely long periods of time.

13. Interpolation Measurements. To make frequency measurements to an accuracy greater than 1 part in 10^6 it is usually necessary to employ a frequency standard and some form of interpolation procedure. The basic principle of interpolation measurements is to use a variable oscillator to cover the frequency range between two precise frequencies generated by a frequency standard. The precision required of the variable oscillator is then greatly reduced because it is only required to compare the unknown frequency with the difference between the two known frequencies.

To illustrate, let f_1 and f_2 be two standard frequencies separated by 1,000 cps and let f_x be an unknown frequency between f_1 and f_2. The variable oscillator may be adjusted for zero beat with each of these frequencies. Now the difference between the readings corresponding to f_1 and f_2 is known to be exactly 1,000 cps; so f_x can be calculated by proportion. If the stability of the variable oscillator permits the difference to be measured to 1 cps the over-all accuracy of the measurement is approximately 1 part in f_1 parts provided the accuracy of f_1 is at least as great.

In practice, many variations of this idea are used. A common procedure is to heterodyne (beat) the unknown frequency with the standard frequency and measure the difference with a heterodyne frequency meter. This is an effective way to extend the range of counting-type frequency meters as suggested in Sec. 12. Standard frequencies may be obtained from harmonics of the precision oscillator.

The accuracy of measurements involving heterodyne processes can be determined by computing the total uncertainty in cycles per second. As an example, suppose the reference frequency is 1 Mc, accurate to 1 part in 10^7. This corresponds to 1 cycle in 10 sec. Let the unknown frequency be approximately 1.05 Mc. The difference also has an uncertainty of 1 cycle in 10 sec. Suppose a 50-kc signal is available from the standard, obtained from the 1-Mc oscillator by frequency division. Its accuracy is 1 part in 10^7, or 0.05 cycle in 10 sec. Now suppose that heterodyning the first difference with the 50-kc standard gives a frequency of less than 1,000 cps which is measured with a heterodyne frequency meter as 570.1 cps. The heterodyne meter has an accuracy of 1 part in 10^4, which also amounts to 1 cycle in 10 sec. Hence, the total uncertainty is 2.05 cps in 10 sec and the measured frequency is 1,050,570.1 ± 0.205 cps.

The distinction between the stability and the accuracy required of the interpolation oscillator should be noted. The stability, *i.e.*, the ability to maintain a given frequency within narrow limits over long periods of time, must be such that the frequency does not change more than the permissible error during measurements. The accuracy, *i.e.*, the precision with which the frequency can be determined from the dial settings, need not be as great since the standard signals provide, in effect, an accurate calibration.

It is common practice for a primary or a secondary standard to provide known frequencies over a wide range for use as "markers." In one arrangement the master oscillator is crystal-controlled at 100 kc. Ten-to-one frequency dividers provide additional signals at 10 kc, 1 kc, and 100 cps. Each of these signals, in turn, is used to drive a harmonic generator, such as a multivibrator, and all these frequencies have the same accuracy as the master oscillator. Similarly, frequency multipliers can be used to generate accurate multiples of the 100-kc frequency.

At lower frequencies (below 1 Mc) multivibrators are very satisfactory as harmonic generators. At higher frequencies, crystal rectifiers (germanium or silicon) are generally more satisfactory. With careful design, harmonics including frequencies as high as 25,000 Mc can be generated.

Although a 1-kc multivibrator may provide harmonics at several megacycles, they are likely to be very weak. Also, in making measurements, it may be difficult to determine which harmonic is being observed. A more satisfactory way to obtain signals of 1-kc separation in the megacycle range is to modulate, for example, a 1-Mc signal by the 1-kc multivibrator signal. Then the side bands of the modulated carrier, produced by harmonics of the multivibrator signal, will be spaced exactly 1 kc apart.

One method of using such equipment is as follows: Fig. 17 indicates the relative positions of the known frequencies. A heterodyne frequency meter or a good communications-type receiver (provided with beat-frequency oscillator) is first tuned to the unknown frequency to locate it approximately. Then, with the modulation frequency f_1 turned off, the receiver is tuned to f_0. Next, the modulation is turned on and the receiver tuned back to f_x. The side bands can be "counted" as they are passed. In this way it is relatively easy to determine which side band lies closest to the unknown frequency. If the standard and the unknown signals are now impressed on a detector, the difference frequency will be obtained and this can be measured by any of the several means already described.

FIG. 17. Standard-frequency marker signals.

14. Comparison by Means of Cathode-ray Oscilloscopes. An oscilloscope affords a convenient means for comparing two frequencies, especially when their ratio is not large. Applying one signal to the horizontal plates and the other to the vertical plates produces a pattern known as a *Lissajous figure*. When the two frequencies are exactly equal, the pattern is a circle or ellipse that is perfectly stationary. Patterns corresponding to frequency ratios of 1:1, 2:1, and 3:1 are shown in Fig. 18. Provided the ratio of the two frequencies is that of two small whole numbers, the number of horizontal and the number of vertical excursions can be counted and the ratio then determined. When the ratio is large or involves large numbers, such as 17:21, it is not easy to count the excursions because of the rather complicated figures produced. It is nearly impossible to make the figures really stationary, and, consequently, only rather simple patterns are practical for most purposes. One of the frequencies must be variable to permit the ratio to be adjusted so that the pattern is at least nearly stationary. Also, relatively large voltages must be available because most oscilloscopes have limited amplification and this is sometimes a disadvantage. The method finds its greatest usefulness at audio frequencies, but with care it can also be used at much higher frequencies.
FIG. 18. Lissajous figures.

15. The Method of Sliding Harmonics. This is a novel use of a stable, tunable oscillator.[6] The principle is illustrated in the block diagram of Fig. 19. Multivibrators can be used as frequency dividers or multipliers. They will remain synchronized over the 1 per cent frequency variation illustrated in Fig. 19. The 100th harmonic of

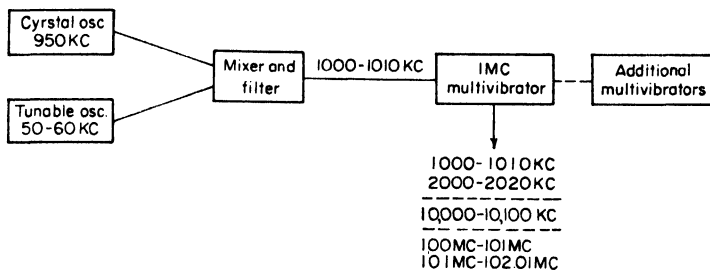
1.01 Mc is the same frequency as the 101st harmonic of 1.00 Mc. The 101st harmonic of 1.01 Mc is slightly higher than the 102d harmonic of 1.00 Mc. Further examination shows that the 1 per cent variation permits continuous coverage of frequencies above the 100th harmonic, in this case above 100 Mc. Similarly, if a 100-kc multivibrator is employed, it will provide continuous coverage for frequencies above 10 Mc, etc. Thus, this system provides, in effect, continuous interpolation with an accuracy approaching that of the crystal-controlled oscillator.


FIG. 19. Interpolating frequency standard using sliding harmonics.

16. Wavemeters. A high-Q tuned circuit provided with a resonance indicator makes a simple inexpensive frequency meter where great accuracy is not required. Such a device is commonly called a wavemeter. One form is represented by the circuit diagram in Fig. 20. The capacitance voltage divider permits the rectifier-microammeter to be loosely coupled to the resonant circuit so that the Q of the circuit will not be appreciably decreased. The variable capacitor is calibrated in terms of resonant frequency, and plug-in coils permit a wide range of frequencies to be covered with a single capacitor.

Wavemeters can be operated as either absorption or reaction devices. In the former case, the coil of the wavemeter is loosely coupled to the circuit whose frequency is to be measured and the capacitor is adjusted for maximum microammeter current. Since the resonant frequency of the wavemeter circuit is changed slightly by the presence of the circuits being measured, the coupling should be as loose as possible while still maintaining a satisfactory indication of resonance. (The resonant frequency of an oscillator circuit may also be affected by the presence of the wavemeter if they are too closely coupled.)

FIG. 20. Tuned-circuit-type wavemeter.

Grid-dip Meters. When used as a reaction device, the wavemeter is also loosely coupled to the circuit under test, but in this case resonance is determined by the reaction of the wavemeter on the test circuit. For example, the grid current of an oscillator will "dip" slightly as the wavemeter is tuned through the operating frequency; the voltage across an amplifier tank circuit will likewise decrease slightly. When used in this way, the wavemeter need not have its own resonance indicator.

The accuracy with which frequency can be determined by means of a wavemeter depends primarily on the Q of the wavemeter circuit and precision with which the capacitor dial can be calibrated. A carefully made worm-screw drive will permit readings to about 1 part in 10^3. Coil Qs from 100 to 500 can be obtained without great difficulty, the higher Qs usually being easier to obtain at higher frequencies. The "exact" maximum deflection is difficult to find because of the flat-top characteristics of resonance curves. For increased accuracy, reference readings should be taken at points off resonance where the characteristic has steep sides. For example, the settings corresponding to equal readings either side of resonance may be noted and the average of these two frequencies will give the desired frequency. (The geometric

mean of these two frequencies is theoretically a closer approximation, but the error introduced by taking the average is usually less than other uncertainties.) The half-current frequencies or the half-power frequencies (current approximately 70 per cent of maximum) make convenient reference points. Using these refinements the wavemeter will give an accuracy of about 0.1 per cent. It is difficult to achieve greater accuracy and an accuracy closer to 1.0 per cent is more usual. Of course, other factors, such as the stability of the tuned circuit with respect to temperature, also affect the accuracy of wavemeters but these factors are almost always of less importance than the limitations set by the accuracy of adjusting and reading the instrument.

In view of the much greater accuracy that can be obtained by other means, the wavemeter is not considered to be a precision instrument. Also, it is necessary to have enough power available to operate the resonance indicator. Greater sensitivity can be obtained by substituting a VTVM (which may be connected across the calibrated capacitor) for the rectifier-microammeter. However, wavemeters are most useful when working with oscillators or transmitters for rough measurements of frequency. Their ease of adjustment and freedom from ambiguities make them useful adjuncts to more precise equipment.

17. Standing-wave Techniques. The "lumped-parameter" wavemeters described in the previous section can be used at frequencies ranging from a few kilocycles to a few hundred megacycles. In the range from approximately 100 to 10,000 Mc standing-wave techniques are useful. Resonant transmission lines, called *Lecher wires,* are useful at the lower end of this range while coaxial lines are better suited to the higher end.

Resonant lines may be used in two ways. One of these is to connect a voltage or current indicator at some convenient point on the line. A shorting bar is then moved along the line. Two positions of the shorting bar that give the same reading of the indicator are one-half wavelength apart. In air the wave velocity on the line is essentially the same as that in free space. Hence,

$$f = \frac{150}{\Delta l} \qquad \text{Mc} \tag{5}$$

where Δl is in meters. The line should preferably be several half wavelengths long so that its resonant impedance will be essentially the same at the two settings of the shorting bar.

A second technique for using Lecher wires consists in moving the resonance indicator instead of the shorting bar. The resonance indicator may consist of a rectifier-microammeter and a very small antenna. With this device, the field near the transmission line can be explored. The distance between two successive maximums or minimums again equals $\lambda/2$. It is better to use two positions not closer than $\lambda/2$ or so to the shorting bar because the field is distorted near the bar. Thus, the distance from the bar to the nearest voltage minimum will be less than $\lambda/2$ because of the "end effect." The distance between the first and second minimums, however, is practically unaffected. This distance will be affected, however, by the presence of dielectric material. Hence, the portion of the line reserved for measurements should be as free as possible of insulators, supports, and other dielectric or conducting materials.

Strong harmonics sometimes cause difficulty on Lecher-wire systems. In extreme cases it may be necessary to plot a curve of the voltage distribution on the line to determine the lowest-frequency mode.

At the higher frequencies, a slotted coaxial line makes a satisfactory resonant system. A probe, inserted through the slotted portion, serves to explore the field along the line. Otherwise, the technique is substantially the same as for Lecher wires.

18. Cavity Wavemeters. At microwave frequencies the concept of lumped-parameter circuits has little meaning and resonant cavities are functionally equivalent to the tuned circuits used at lower frequencies. They are extensively used as wavemeters. They are mechanically simple and are capable of surprisingly high accuracy. Typical

constructions are sketched in Fig. 21.[7] The cavity takes the form of a cylinder tuned by a piston as in Fig. 21*a* or a plunger as in Fig. 21*b*. Tuning is accomplished by means of a micrometer screw mechanism which permits very good resolution. Such cavity resonators may have many resonant modes, and this can lead to ambiguities and parasitic resonances. A discussion of these problems is too involved to be presented here, but through careful design, difficulties arising from these sources can be largely eliminated. See Chap. 6, Sec. 48.

FIG. 21. Typical forms of cavity wavemeter.

In use, the cavity wavemeter is loosely coupled to the source by means of a loop or orifice. Resonance is commonly determined by noting the effect of the energy absorbed by the wavemeter. It is also possible to provide the wavemeter with a rectifier-microammeter or other detector to serve as a resonance indicator.

A well-constructed cavity wavemeter easily permits an accuracy of the order of 1 part in 1,000 to be obtained and with special care 1 part in 10^6 can be achieved. For such accuracy it is necessary to take into account second-order effects such as the influence of moisture vapor in the cavity and temperature.

19. Wave Form. Measurements of wave form can be approached from two points of view. When the details of the actual wave shape are the primary interest, a cathode-ray oscilloscope is indispensable. In this case wave forms are described in terms of rise time, pulse width, overshoot, and so on. When information of a more general kind is desired a harmonic wave analyzer is the appropriate instrument and wave forms are described in terms of harmonic content, distortion, and similar ideas.

A general-purpose oscilloscope is provided with amplifiers for both vertical and horizontal deflection, with sweep-voltage generators and synchronizing circuits as well as with the power supply necessary for the cathode-ray tube itself. In most cases the versatility of the instrument is limited primarily by the band width and gain of the amplifiers and the flexibility of the sweep-voltage generator. The useful band width of the CRT itself is of the order of 500 to 1,000 Mc and it can be made even higher. However, conventional video amplifiers provide a band width of up to only about 10 Mc. Through the use of distributed amplifiers this limit can be increased to 200 Mc or higher.

The sweep-voltage generator provides a saw-tooth voltage, *i.e.*, a voltage that increases linearly with time and then decreases very rapidly to its initial value. During the retrace time, a blanking voltage is applied to the CRT so that the beam is extinguished while the sweep voltage returns to begin a new trace. Thus, the horizontal position of the beam is proportional to time, and consequently, the pattern displayed on the screen shows the vertical-axis voltage as a function of time. Other voltage waves are sometimes used for the sweep voltage but the saw tooth is ordinarily most useful.

The sweep generator is provided with circuits that permit its frequency to be synchronized with that of the wave to be studied or some subharmonic of it. In this way stationary patterns are displayed on the screen.

When the wave to be studied is not periodic or the interesting part represents only a portion of a cycle, a so-called *driven sweep* is preferred. The driven sweep generates a saw-tooth voltage which is initiated by a trigger impulse usually derived from the voltage under study. A delay line in the vertical amplifier delays this voltage until the trigger has had sufficient time to start the sweep cycle. In this way the beginning of the wave is presented. Without the delay line, the beginning of the wave would be lost. Of course, trigger pulses may also be obtained from a signal related to the one under observation if desired, for example, a subharmonic.
Cathode-ray oscilloscopes are also used to provide a *parametric display*. For example the x-axis voltage may be the input voltage to an amplifier while the y-axis voltage is its output. If the horizontal and vertical amplifiers in the CRO are identical, and the output voltage of the amplifier is proportional to its input voltage, a straight line will result. Deviations from a straight line may represent distortion, phase shift, or other characteristics of the amplifier. When used in this way it is particularly important that the horizontal and vertical amplifiers of the CRO have similar characteristics. Otherwise, their differences may be attributed to the circuit under study.

20. Pulse Shape. The terms used in describing pulse shape are essentially descriptive. Quantities of chief interest are *amplitude, width, rise time, fall time, overshoot,* and *sag*. The significance of these terms is illustrated in Fig. 22.
FIG. 22. Pulse-shape parameters.
FIG. 23. Oscillatory pulse.

It is apparent from the figure that they are best adapted to describing pulses that are approximately rectangular in shape. Attempts to give precise definitions to these terms are not very rewarding unless the class of pulses to which they are applied is severely restricted. For example, there would be little point in discussing the rise time of a highly oscillatory pulse such as that shown in Fig. 23 since this is not likely to be a significant parameter.

Rectangular pulses, however, are used for many applications, especially for testing amplifiers, delay lines, etc. When a rectangular pulse is applied to an amplifier, the rise time of the output pulse is approximately inversely proportional to the band width of the amplifier, provided the rise time of the applied pulse is short compared with that of the output pulse. Amplifier circuits providing short rise times are likely to introduce overshoot. Consequently, rise time and overshoot are the parameters of most frequent interest.

The exact time at which a pulse begins or ends is rather difficult to specify. Hence, rise time is commonly specified as the time required for the pulse to increase from 10 to 90 per cent of its final value. Similarly, overshoot is usually expressed as a percentage of the final value. Other useful definitions are indicated in the figure.

21. Pulse Measurements. Pulse measurements are usually made with a wide-band oscilloscope that has a horizontal sweep generator calibrated in microseconds per centimeter. Provisions for calibrating the gain of the vertical amplifiers are also desirable. The rise time and pulse width can be determined by expressing these quantities in centimeters and then multiplying by the scale factor as shown by the dial settings of the oscilloscope. A convenient way to check the sweep speed calibration is to measure the period of a sine wave or square wave of known frequency.

It is important that the oscilloscope amplifiers be reasonably linear and care must be taken not to overload them. Obviously, an overloaded amplifier can clip a pulse, making it appear flat-topped when it is not, or otherwise distort the pulse. In addition, the rise time of the oscilloscope amplifiers must be small compared with the rise time of the observed pulse. An approximate formula for the total rise time of several amplifiers in cascade is

$$T \cong \sqrt{T_1^2 + T_2^2 + \cdots + T_n^2} \tag{6}$$

where $T_1, T_2, \cdots, T_n$ are the rise times of the respective amplifiers. This formula is accurate to a few per cent if none of the amplifiers has appreciable overshoot in its response.

When the band width of an amplifier is known, its rise time can be computed approximately from the relation

$$T \approx \frac{0.35}{W} \tag{7}$$

where T is the rise time in microseconds and W is the amplifier band width in megacycles. The half-power band width of the amplifier may be used for W, provided its pulse response is not oscillatory. As has been indicated above, there is often considerable uncertainty about the precise meaning of rise time and, therefore, these approximate formulas are sufficiently accurate for most practical purposes. When more accurate results are needed it is generally necessary to take into account the requirements of the particular problem under study as well as the detailed characteristics of the instruments.

When dealing with long pulses, for example, as with a low-frequency square wave, inadequate low-frequency response of the amplifier may introduce sag. When the total sag is of the order of 10 per cent or less, the total per cent sag is approximately the sum of the per cent sags introduced by each amplifier.

22. Wave Analyzers. For many purposes the wave shape of a signal is of less importance than its Fourier spectrum. If it is possible to obtain a photograph of the wave (a number of cameras are available which can be used to photograph the oscilloscope presentation) a graphical analysis can be used to determine the spectrum. However, it is often more convenient to use a wave analyzer. Although a wave analyzer does not yield information concerning the relative phase of a harmonic the phase is often of no importance.

A wave analyzer is essentially a very selective (narrow-band) calibrated amplifier combined with VTVM. The amplifier is tuned to the signal in question by adjusting for maximum deflection of the VTVM which then indicates the amplitude of the signal. Wave analyzers commonly employ the superheterodyne principle to achieve very high selectivity. One commercial wave analyzer has an effective band width of only 4 cps.[8] Others have adjustable band widths.

If a "true" Fourier spectrum is desired, the wave analyzer should have a very narrow pass band. However, the narrow band is a disadvantage in some cases. If the signal to be measured is drifting slightly or if its frequency fluctuates, as is often the case, the narrow-band analyzer may give misleading results. For example, suppose an a-f oscillator has its frequency modulated slightly by 120-cps power-supply ripple. The narrow-band analyzer would distinguish between the side bands produced by the modulation (these would be spaced at 120-cps intervals on each side of the average frequency) whereas the wide-band analyzer would indicate the average total voltage. Again, the narrow-band analyzer must have a slow-acting VTVM and it is easy to miss small signals by tuning past them before the meter can register. The wide-band analyzer is more tolerant in this situation. Thus, each type of instrument has its own field of application.

One of the chief limitations of the heterodyne wave analyzer is cross modulation which can occur in the mixer or preamplifier. With careful design spurious readings can be kept 60 db below the largest component at the input but difficulty may arise when an attempt is made to measure a small signal in the presence of a much larger one.

23. Phase Measurements. It is possible to discuss the phase difference of any two periodic signals having the same period and essentially the same wave form. Usually, however, the interpretation of phase difference is difficult except for wave forms that are sinusoidal or nearly so. For other wave shapes, the terminology of pulse techniques, *i.e.*, time delay, is likely to be more useful. Also, it is convenient to speak loosely of the relative phase of two sinusoidal waves of slightly different frequency. For example, the beat phenomenon associated with two waves of approximately the same frequency is often described by saying the waves are alternately in phase and out of phase. In its strict sense, phase difference refers to sinusoidal waves of the same

frequency, and in the following discussion of phase-measurement techniques it is assumed that the signals in question are sinusoidal and have the same frequency.

One of the easiest ways to measure phase difference at audio and low radio frequencies is by means of an oscilloscope. The two signals are applied to the horizontal and vertical deflection circuits, respectively. The resulting Lissajous figure then takes the form shown in Fig. 24. The phase difference θ between the two waves is given by the formula
$$\theta = \sin^{-1}\left(\pm \frac{y_1}{y_0}\right) \qquad (8)$$

Fig. 24. Lissajous figure for measuring phase difference.

If the phase shift introduced by the horizontal and vertical amplifiers of the oscilloscope is the same, the net phase shift indicated is the desired angle. If not, a correction must be made for the phase shift introduced by the oscilloscope. This can be determined by connecting one signal to both horizontal and vertical inputs. Then the angle can be measured and added to or subtracted from the indicated angle as required. It is desirable that the oscilloscope introduce very little phase shift. It is also clear that the method is suited only for waves that are very nearly sinusoidal.

The ambiguity concerning the proper quadrant for θ can be resolved by adding a small additional known phase shift to one of the signals. Sometimes this can be accomplished by changing slightly some parameter of the circuits under test. In other cases it may be necessary to adjust the test frequency to some value for which the phase shift is known approximately and then noting the direction in which the phase changes as the frequency is moved to the desired value. This, or something equivalent, is about the only way to resolve the whole-cycle ($360N$ deg) ambiguity that always is present. In most cases, it is possible to estimate the phase to within 360 deg; in others, the whole-cycle ambiguity is not objectionable.

If a calibrated phase shifter is available it can be used to introduce a known phase shift in one of the signals. The oscilloscope can then be used to determine when the net phase shift is zero and thus that the added phase is equal to the actual phase difference.

When a calibrated phase shifter is available, a variety of schemes can be used. For example, the two voltages whose phases are to be compared can be applied to a difference amplifier. The amplitude and phase are then adjusted by means of the phase shifter and an attenuator applied to one of the signals. When the output of the difference amplifier is zero, the phase difference can be read from the phase shifter. Care must be taken to be certain that the attenuator does not introduce appreciable phase shift. Also, as in any other measurement, precautions are necessary to assure that the phase-measuring equipment does not itself affect the phase difference to be measured.
Fig. 25. Phase comparison with slotted line.

In the microwave region, a matched transmission line or slotted line may be used as a phase shifter. The general arrangement is shown in Fig. 25. The line should be matched to a standing-wave ratio of 5 per cent or better to avoid corrections to compensate for the mismatch. If the source is modulated at an audio frequency the detector may consist of a crystal rectifier and audio amplifier. The system is "zeroed" by connecting the differencing circuit to the source side of the two circuits and then adjusting the probe for minimum detector output. The two signals at the detector input should be approximately the same amplitude so that a well-defined minimum will be obtained. If a suitable attenuator is available a null may be produced by

adjusting the signals to be equal in amplitude and 180 deg out of phase. (If a difference amplifier is used as a detector, the null occurs when the two signals are in phase.) Two successive nulls correspond to probe positions separated by one wavelength or 360 deg.

24. Direct-reading Phase Meter. Several schemes have been devised to provide direct-reading phase meters. With the help of pulse techniques, the signals to be compared are converted to square waves or pulses of equal amplitude. In one system, positive pulses from the two signals are applied to the grids of a flip-flop circuit. This flip-flop is switched to the "on" state by pulses derived from one signal and to the "off" state by pulses from the other signal. Consequently, the fraction of a cycle that one tube is on is proportional to the phase angle between the input signals as indicated in Fig. 26. Hence the average current as indicated on a d-c meter is also proportional to this angle. The current in the other tube of the flip flop is proportional to 360 deg $-$ θ.
Fig. 26. Pulse-angle relationships in direct-reading phase meter.

The pulses are generated so that they occur when their associated signals change sign from negative to positive, *i.e.*, at the positive-going zero crossings. Continuous readings from zero to 360 deg are obtained.

The polarity of either signal can be reversed; thus, 180 deg $-$ θ can also be measured. This instrument is not sensitive to wave-form errors provided the distortion does not cause the zero crossings to be unequally spaced and does not cause more than two zero crossings per cycle.

The useful frequency range of such a device is limited by the switching times of the pulse generators and flip flops. In one commercial instrument an accuracy of about 5 deg is obtained from 10 cps to 40 kc. The range can be extended upward through the use of heterodyne techniques since the phase angle between two signals can be preserved if they are heterodyned with the same signal.

POWER MEASUREMENT

Although several instruments have been devised for the direct measurement of power at high frequencies in terms of current, voltage, and power factor, they have not found widespread use. The reason probably is that under the conditions for which high-frequency power measurements are usually made indirect methods are both satisfactory and more practical.

25. Methods Employing Standard Impedances. For measuring the power output of an a-f or r-f amplifier the simplest method is to dissipate the power in a standard resistance and measure the voltage with a VTVM or the current with a thermocouple ammeter. The power is then computed from E^2/R or I^2R.
Fig. 27. Three-ammeter method for measuring power.

When a standard resistance of suitable value is not available the impedance of the circuit used can be measured at the operating frequency by means of a bridge and the power calculated from either E^2/R_p or I^2R_s, in which R_p is the equivalent parallel resistance and R_s is the equivalent series resistance of the circuit in question.

The same principle can be used to measure the power input to an antenna, matched transmission line, or other circuit whose impedance is known.

A variation of the principle known as the *three-ammeter method* is sometimes useful. This method also requires a known impedance. The circuit arrangement is shown in

Fig. 27. Neglecting the losses in C_s

$$P = 2X_c \sqrt{S(S - I_a)(S - I_b)(S - I_c)} \tag{9}$$

in which P = power, watts
X_c = reactance of C_s, ohms
$S = \frac{1}{2}(I_a + I_b + I_c)$

A similar scheme is shown in Fig. 28. In this case

$$P = \frac{1}{2R} \sqrt{V_a^2 - V_b^2 - V_c^2} \tag{10}$$

If the resistor is replaced by a capacitor as in Fig. 29, then

$$P = \frac{2}{X_c} \sqrt{S(S - V_a)(S - V_b)(S - V_c)} \tag{11}$$

in which $$S = \frac{V_a + V_b + V_c}{2}$$

It is clear from the vector diagrams that best accuracy is obtained when the three currents (or voltages) are the same order of magnitude and the currents are nearly sinusoidal. Harmonic currents in the capacitance in Fig. 27 can introduce large errors even though the voltage across the load may have a good wave form.
Fig. 28. Three-voltmeter method for measuring power.
Fig. 29. Variation of three-voltmeter method.

26. Bolometer Methods. The methods described in Sec. 25 are useful at frequencies up to about 500 Mc. Above this frequency it becomes increasingly difficult to measure current and voltage. At these higher frequencies and at microwave frequencies energy is nearly always distributed over matched transmission lines or wave guides. When the amount of power to be measured is relatively small it is dissipated in a specially constructed resistor called a bolometer. The term bolometer is used to refer to either of two kinds of temperature-sensitive resistors: *barretters*, which are metallic resistors with positive temperature coefficients of resistance, and *thermistors* made of metallic oxides and which have negative temperature coefficients of resistance. Barretters are usually less rugged than thermistors but since they operate at higher temperatures they are less affected by ambient temperature.

Bolometers can be used to measure power of less than 1 μw. When relatively large amounts of power are to be measured, a bolometer can be used to "sample" the power, *i.e.*, to measure a small amount of power that is proportional to the desired power.

Two methods are in common use to measure power by means of bolometers.[7] In each case the bolometer forms one arm of a Wheatstone bridge. A *balanced-bridge* arrangement is shown schematically in Fig. 30. To measure the r-f power, the a-f power supply is turned off, and the bridge is balanced by adjusting the d-c bias current. Then the r.f. is turned off and the bridge again balanced by adjusting the a-f voltage. Now the a-f power supplied to the bolometer exactly equals the power previously supplied by the r-f source. Since the bridge is balanced, this power equal $V^2/4R$.

The *unbalanced-bridge* method is similar, but the a-f source is not required. Instead, the bridge is balanced by adjusting the bias current with the r-f power turned off.

When the r.f. is turned on the bridge is, of course, unbalanced again. The null detector is calibrated to indicate directly the r-f power. This method is more convenient than the balanced-bridge method, but the change in resistance of the bolometer during the measurement is not always permissible.
FIG. 30. Bolometer bridge.

27. Directional Couplers. A directional coupler can distinguish between the waves traveling in opposite directions when connected to a wave guide or transmission line. It can be arranged to respond to either the incident or the reflected wave or to both. When arranged to respond to both waves the signal associated with one wave appears at one output, while that associated with the other wave appears at a different output.

A bolometer connected to one terminal of a directional coupler affords a convenient way to monitor the power transmitted over the system. The power required by a properly designed bolometer is so small that it has a negligible effect on the system. If desired, the transmitted and reflected power can be measured separately and the actual load power computed as their difference. However, the reflected power is relatively small even for rather poor matching. For example, a voltage standing-wave ratio of 2 corresponds to a reflection coefficient of $\frac{1}{3}$ and the reflected power is only $\frac{1}{9}$ the load power. For a voltage standing-wave ratio of 1.25 the reflected power is only a little more than 1 per cent of the load power. Thus, it is evident that it is usually sufficient to measure only the transmitted wave.

Voltage measurements can also be used to sample the power in a matched transmission line. However, unless the line is perfectly matched, the voltage reading depends on the location of the probe relative to the standing-wave pattern, whereas the directional coupler is not affected by the standing waves. The superiority of the directional coupler is illustrated by the above examples.

CIRCUIT PARAMETERS

Three general methods are available for measuring circuit parameters at high frequencies. These are the voltmeter-ammeter method, the substitution method, and the bridge method. In addition, a number of direct-reading impedance meters are commercially available. The voltmeter-ammeter method is not well suited to high-frequency applications because sensitive a-c milliammeters are not available and the angle of an impedance is usually desired as well as its magnitude. Consequently, measurements in terms of voltage, current, and power are cumbersome. Substitution measurements are easy to make but have the disadvantage that an adjustable standard having the same impedance as the unknown is required.

Bridge measurements afford the best accuracy. However, when a bridge suitable at the required frequency is not available satisfactory results can be obtained in other ways. With a good vacuum-tube voltmeter, a standard variable capacitor, and a Q meter, methods can be improvised to meet a surprisingly wide range of needs.

28. Equivalent Circuits. For some purposes it is desired only to measure the equivalent resistance and reactance of a circuit or component at a particular frequency. In other cases it is more useful to determine an equivalent circuit that is valid over a substantial frequency band. For this purpose it is necessary to make measurements at more than one frequency and it is advisable to make additional measurements over the band width of interest.

When making measurement on coils it is always wise to estimate the effects of the distributed capacitance even when its value is not required. The equivalent circuit in

Fig. 31*a* is a good representation for coils of usual design. Analysis of this circuit shows that the "apparent" inductance, *i.e.*, the equivalent inductance, is approximately

$$L_e \approx L/(1 - \omega^2 L C_0) \tag{12}$$

or

$$L_e \approx \frac{L}{1 - (\omega/\omega_0)^2} \tag{13}$$

in which L is the true inductance, ω is the frequency at which the measurement is made, and ω_0 is the natural resonant frequency of the coil.
Fig. 31. Equivalent circuits for coil with distributed capacitance.

The equivalent resistance is given by

$$R_e \approx \frac{R}{[1 - (\omega/\omega_0)^2]^2} \tag{14}$$

Equations (12) to (14) are obtained by assuming that $R\omega C_0 \ll (1 - \omega^2 L C_0)$, which is equivalent to assuming $1 \ll \frac{|X_c| - |X_L|}{R}$. Obviously, they cannot be used if the operating frequency is near the natural frequency of the coil. However, if the Q of the coil at its natural frequency is greater than about 10, these equations will give meaningful results for frequencies less than about 70 per cent of the natural frequency.

Figure 32 shows how the impedance of the circuit in Fig. 31*a* varies with frequency. It is clear that the shunt capacitance C_0 can be neglected only at frequencies that are *well below* the natural frequency.

These considerations are significant when measuring coil characteristics. Thus, if the inductance and resistance (or Q) of a coil are measured on a bridge or conventional Q meter the results may be quite misleading if the coil is subsequently used as part of a parallel-resonant circuit. Therefore, the choice of measurements to be made will depend on the application involved.

Fig. 32. Variation of impedance with frequency for circuit in Fig. 31*a*.
Fig. 33. Equivalent circuit for capacitor with residual inductance.

Analogous but less troublesome difficulties are caused by the residual inductance of capacitors as indicated in the equivalent circuit of Fig. 33. The residual inductance L_0 is seldom as large as the inductance of connecting wires and consequently it can be neglected except for very exacting measurements. However, certain types of rolled-paper capacitors have an appreciable inductance and cannot be used at high frequencies.

29. Substitution Measurements. Substitution measurements are easy to make and quite satisfactory when suitable standards are available. Basically, the method consists of measuring some characteristic of a circuit that includes the unknown to be

determined and then substituting a standard element for the unknown. When the standard has been adjusted to duplicate the original conditions, the standard has the same value as the unknown. A feature of the method is that it depends on the accuracy of the standard rather than on the accuracy of an instrument such as a voltmeter or ammeter.

The method is illustrated in Fig. 34. In (*a*) an ammeter is connected to a low-impedance source E in series with the unknown R_x. After the current is noted, the standard is connected in place of the unknown and adjusted to produce the same current. Then $R_s = R_x$. The impedance of the source is not important provided it is low compared with R_x and does not change during the measurement. In (*b*) a high-impedance source is used or a resistance R is connected in series with a low-impedance source. In this case R_s is adjusted so that V is the same when R_s is substituted for R_x. Note that a low-impedance source should not be used in (*b*) because V would then depend very little on R_x.

FIG. 34. (*a*) Substitution method using current balance; (*b*) substitution method using voltage balance.

This method can be used to measure a capacitance or an inductance. However, if the resistance of the inductor is appreciable this method is unsatisfactory because it provides no way to determine the phase angle.

A convenient way to measure a capacitance, especially a small one, is to use it as part of the tuning capacitance in a resonant circuit. Several methods of coupling the tuned circuit to a signal generator are indicated in Fig. 35. The procedure is to adjust the circuit to resonance by varying the standard capacitor to obtain maximum voltage as indicated by the VTVM. The unknown capacitor is then disconnected and the circuit readjusted for resonance. The difference between the two settings of C_s is the value of C_x.

FIG. 35. Methods for coupling a tuned circuit to a signal generator.

This procedure can also be used to measure a large inductance provided the resonant frequency is known. In this case, the susceptance of the inductance equals the susceptance added by C_s when the circuit is returned. Since the inductive susceptance is negative, the capacitance must be *decreased* when the inductor is removed. Hence,

$$\frac{1}{\omega L_e} = \omega \, \Delta C_s$$

or

$$L_e = \frac{1}{\omega^2 \, \Delta C_s} \tag{15}$$

If it should happen that C_s must be increased when the inductor is removed, this indicates that the operating frequency is above the natural resonant frequency of the inductor. Note also that this method yields the equivalent parallel inductance. If the Q of the inductor is greater than 10, the equivalent parallel inductance and the equivalent series inductance differ by less than ½ per cent.

A variation of this procedure is to connect the unknown reactance in series with the standard capacitor. The change in the reactance of the standard then equals the unknown reactance. For a capacitance,

$$C_x = \frac{C_{s1} C_{s2}}{C_{s2} - C_{s1}} \tag{16}$$

and for an inductance

$$L_x = \frac{1}{\omega^2}\frac{C_{s1} - C_{s2}}{C_{s1}C_{s2}} \tag{17}$$

in which C_{s2} and C_{s1} are the values of the standard with and without the unknown, respectively.

30. Susceptance Variation. One of the most useful techniques for determining the equivalent parallel circuit of a component is the susceptance variation method and its related schemes. The circuit arrangement is shown in Fig. 36*a*. It is simpler to
FIG. 36. (*a*) Circuit for susceptance-variation measurements; (*b*) equivalent circuit.

regard the unknown as an admittance consisting of a conductance G_x and a susceptance B_x in parallel. Z_g should be an impedance having a magnitude as large as or larger than the impedance across which the VTVM is connected. A resistance is best but a small capacitor can be used.

One of the chief advantages of this circuit is that each component except Z_g can have one of its terminals connected to a common ground.

Applying Norton's theorem to the circuit in Fig. 36*a* gives the circuit in Fig. 36*b*. Combining the input admittance of the VTVM with that of Z_g gives the circuit in Fig. 37, in which the voltmeter has zero input admittance. Assuming Y_x is inductive, the total conductance of the circuit is measured as follows. First, C_s is adjusted for resonance (maximum voltage) at a value C_1 and the voltage V_0 noted. Then C_s is increased to a value C_2 such that the voltage decreases to a new value V_1. Then the total conductance is

$$G_t = \frac{\omega(C_2 - C_1)}{\sqrt{(V_0/V_1)^2 - 1}} \tag{18}$$

and

$$G_x = G_t - G_0 \tag{19}$$

If Z_g is a resistance R_0 then G_0 is very nearly equal to $1/R_0$, since the losses in the capacitor are usually small enough to be neglected. If Z_g is a capacitance, C_0 can usually be neglected.

The susceptance of Y_x equals the total capacitive susceptance at resonance. Thus,

$$L = \frac{1}{\omega^2(C_1 + C_0)} \tag{20}$$

It is often sufficient to estimate the stray capacitance C_0 or to neglect it entirely.

If a coil whose susceptance and conductance are known is available, then Eqs. (19) and (20) can be used to find G_0 and C_0 and thus to improve the accuracy of the measurements.

The parameters of a known coil can be determined as follows. First, the total conductance of the circuit as in Fig. 37 is determined by Eq. (18). Then the known coil is added to the circuit (care being taken to assure that there is no mutual inductance between the two coils). Now the total conductance is again measured and the increase is the conductance of the known coil. Its susceptance is the change in susceptance ($\omega\,\Delta C_s$) required to retune the circuit when the known coil is added. Finally, the known coil is substituted for Y_x in Fig. 37 and G_0 determined. Also, C_0 can be found since at resonance

$$\omega(C_s + C_0) = \frac{1}{\omega L_x} \tag{21}$$

and C_s is known.

To measure the capacitance and conductance of a capacitor, they are simply added to the circuit of Fig. 37 with a coil for Y_x. The increase in total conductance is the conductance of the unknown and its capacitance is the change in C_s necessary to retune the circuit when C_x is added. Neither C_0 nor G_0 need be known for this measurement.

FIG. 37. Circuit equivalent to Fig. 36b.

Near resonance the voltage changes slowly with C_s so the value corresponding exactly to resonance is not well defined. The accuracy can be improved by finding two values C_2 and C_3, one greater than the value for resonance and the other less than the value for resonance and for which the voltages are equal. Then

$$C_1 = \frac{C_2 + C_3}{2} \tag{22}$$

Using this value for C_1 in Eq. (18) gives

$$G_x = \frac{(\omega/2)(C_2 - C_3)}{\sqrt{(V_0/V_1)^2 - 1}} \tag{23}$$

The value V_0/V_1 is not critical. A convenient value is $\sqrt{2}$ since the radical in the denominator of Eq. (23) then equals unity. However, when the conductance is very small a larger value may improve the accuracy by increasing $(C_2 - C_3)$. On the other hand, if too large a value is chosen the voltage variation again becomes small and the accuracy suffers.

31. Reactance Variation. Instead of the parallel circuit a series arrangement may be used as indicated in Fig. 38. The same principles apply to this circuit as to Fig. 37 but in this case the current in the circuit is observed. Results are expressed in terms of the equivalent series resistance and reactance. The susceptance variation method described in Sec. 30 is generally more convenient to use at radio frequencies.

FIG. 38. Circuit for reactance-variation measurements.
32. Frequency Variation. In modified versions of both the preceding methods, the frequency can be varied instead of the capacitance. Greater care is required when frequency is varied because the values of the elements in the equivalent circuits may depend upon frequency. For narrow-band circuits, *i.e.*, circuits for which Q is large, the frequency-variation method gives good results. The signal generator must be arranged so that small increments can be read with good accuracy. The basic measurement is the half-power band width of the tuned circuit. Ideally, a current source should be used to excite the tuned circuit but the arrangement in Fig. 39 is satisfactory. When the output voltage of the signal generator is held constant this circuit is equivalent to a current source driving the unknown circuit in parallel with R_0. The conductance of R_0 should be subtracted from the measured total.
FIG. 39. Circuit for frequency-variation measurements.

The procedure for measuring the total conductance G_t is to adjust the frequency for resonance (maximum voltage) and note ω_0 and V_0. Next, adjust the frequency to a new value ω_1 which gives a reading V_1. Then

$$G_t = \frac{2C(\omega_1 - \omega_0)}{\sqrt{(V_0/V_1)^2 - 1}}$$

The approximation is within ½ per cent when Q is greater than 10.

An exact relation is obtained by using two frequencies for which the voltage readings are both V_1. Assume ω_2 is less than ω_0; then

$$G_t = \frac{C(\omega_1 - \omega_2)}{\sqrt{(V_0/V_1)^2 - 1}} \tag{24}$$

With $(V_0/V_1)^2 = \sqrt{2}$, this yields the very simple relation

$$G_t = C(\omega_1 - \omega_2) \tag{25}$$

Also,

$$G_x = G_t - G_0 \tag{26}$$

This scheme is well suited to measuring the Q or the band width of a tuned circuit since it avoids the necessity of making separate measurements on L and C. The impedance at resonance is a pure resistance,

$$Z_R = 1/G_x \tag{27}$$

and the circuit Q is

$$Q_e = \frac{\omega_0}{\omega_1 - \omega_2} = \frac{f_0}{f_1 - f_2} \tag{28}$$

in which f_1 and f_2 are the half-power frequencies for which $V_0/V_1 = \sqrt{2}$. Other useful relations are

$$C = \frac{G_x}{\omega_1 - \omega_2} \tag{29}$$

$$L = \frac{\omega_1 - \omega_2}{\omega_0{}^2 G_x} = \frac{1}{Q\omega_0 G_x} \tag{30}$$

and

$$\omega_1\omega_2 = \omega_0{}^2 \tag{31}$$

As determined by this method, G_x, C, and L are the values in the equivalent parallel circuit. Thus, G_x includes the losses in the capacitor and C includes the distributed capacitance of the coil.

The frequency-variation technique can also be used for measurement on individual components by noting the changes they produce in ω_0 and G. It must not be forgotten that the values in the reference equivalent circuit will depend on the frequency to some extent.

33. Distributed Capacitance of Coils. It is possible in principle to determine the distributed capacitance of a coil by measuring the resonant frequencies when two known values of capacitance are added and using the relationships

$$\omega_1{}^2 = 1/L(C_1 + C_0)$$
$$\omega_2{}^2 = 1/L(C_2 + C_0)$$

to solve for C_0. However, better accuracy can be obtained by plotting $1/f^2$ as a function of the added capacitance as indicated in Fig. 40. If the resulting straight line is then extrapolated, the X-axis intercept gives the distributed capacitance C_0 as in Fig. 40.
FIG. 40. Graphical determination of distributed capacitance.

It should be remembered that the capacitance of a coil is in reality distributed and the lumped-circuit approximation is not suitable for every purpose. Above the lowest parallel-resonant frequency most coils behave like distributed-parameter systems exhibiting both series and parallel resonances. Since coils are seldom intentionally used in this frequency range this behavior is usually of practical importance only when it produces unwanted results. Then an equivalent circuit must be found to represent the coil over the range in question. It may also be added that the self-resonant frequency of a coil is usually somewhat higher than the value calculated from measurements of L and C_0 by the above methods.

34. Measurements of Q. The Q of a coil is defined by the relation

$$Q_L = \frac{\omega L}{R} \tag{32}$$

in which L is the inductance and R the resistance of the coil.

The Q of a resonant circuit is defined by the relation

$$Q_e = \frac{\omega_0}{W} = \frac{2\pi f_0}{2\pi W} = \frac{f_0}{W} \tag{33}$$

in which f_0 is the resonant frequency and W is the half-power band width. In the case of a parallel-resonant circuit the half-power band width is the difference between the two frequencies for which the voltage is $1/\sqrt{2}$ times the voltage at resonance when the circuit is excited by a constant-current source. In the case of a series-resonant circuit, the half-power band width is the difference between the two frequencies for which the current is $1/\sqrt{2}$ times the current at resonance when the circuit is excited by a constant-voltage source.

FIG. 41. Ideal parallel GCL circuit.

When the only losses in a resonant circuit are in the coil, the circuit Q is the same as the coil Q. Hence, the circuit Q is often referred to as the equivalent Q. In the idealized parallel circuit in Fig. 41 the circuit Q is given by

$$Q_e = \frac{\omega_0 C}{G} = \frac{1}{G\omega_0 L} \tag{34}$$

To find the Q of a soil, its inductance and resistance can be measured by any of the methods described in Secs. 33 to 39 and the Q can be computed from the appropriate one of Eqs. (32), (33), and (34). Equation (28) gives the circuit Q directly according to Eq. (33). When making calculations based on conductance measurements one obtains circuit Q or coil Q depending upon whether the total conductance or only the coil conductance is used. Thus, if the coil conductance is used in Eq. (34), the result is the same as if the equivalent series-circuit values are computed and used in Eq. (32). Equations (18) and (20) give, for the susceptance-variation method,

$$Q_e = \frac{C_1 + C_0}{C_2 - C_1}\sqrt{(V_0/V_1)^2 - 1} \tag{35}$$

Equation (35) emphasizes the necessity of considering the distributed capacitance when making Q measurements. However, the frequency-variation method yields correct circuit-Q values without the necessity of measuring C_0.

35. The Q Meter. The Q meter provides the most convenient and the most widely used method for measuring Q. A simplified circuit diagram of a Q meter is shown in
FIG. 42. Simplified circuit of Q meter. FIG. 43. Equivalent circuit of Q meter.
Fig. 42. In this device, a known voltage is introduced in series with the coil under test by passing a known current through a standard resistance. Notice that the tuned circuit is in series resonance when the capacitor is adjusted for maximum voltage. An equivalent circuit as shown in Fig. 43 can be obtained with the help of Thévenin's

theorem. At resonance the capacitor voltage is

$$V_c = \frac{E}{R_s + R_c}\frac{1}{\omega C} = E\frac{\omega L}{R_s + R_e} \tag{36}$$

or

$$V_c/E = Q_e \tag{37}$$

Since $E = I_0 R_s$, the VTVM can be calibrated to read Q directly when I_0 is set to predetermined values.

It is clear that the Q meter measures equivalent Q and not coil Q. The coil Q can be found by making corrections for the distributed capacitance of the coil and the resistance R_s. Of course, these corrections are not required for most routine measurements; hence, this feature of the Q meter is not a serious disadvantage. When C_0 and R_s are known the coil Q is readily computed:

$$Q_L = Q_0 \frac{C_s - C_0}{C_s}\frac{R_0}{R_0 - R_s} \tag{38}$$

In this expression Q_0 = observed Q
$R_0 = 1/\omega L_s Q_0$ = observed resistance

It is clear that the correction for C_0 may easily be quite large. The correction for R_s is seldom significant.

Another feature of the Q meter that is occasionally important arises from the fact that the maximum capacitor voltage does not occur exactly at series resonance (unity power factor). When the circuit Q is less than 10, the difference between the capacitances (or frequencies) producing maximum V_c and those for true resonance is appreciable.

The Q meter is also very useful for making substitution measurements and for measuring distributed capacitance of coils as described in Sec. 29. Commercial instruments are calibrated to measure inductance directly by setting the frequency to predetermined values. The direct reading is, of course, equivalent inductance which must be corrected for C_0 when circumstances demand it.

The Q meter furnishes a very practical way for making a wide variety of routine measurements.

BRIDGE MEASUREMENTS

As discussed earlier, impedance measurements in the frequency range below 150 Mc can be made with more precision by means of bridges than with any other method. Above this frequency stray capacitances and inductances cause serious errors in the measurements.

36. Wheatstone Bridge. The bridges used for measuring impedance at audio and radio frequencies have the general form of the Wheatstone bridge shown in Fig. 44.
When the bridge is balanced no potential difference exists between points B, B' and the detector output is a null. Under this condition

$$Z_a Z_c = Z_b Z_d \tag{39}$$

Fig. 44. General form of Wheatstone bridge.

The impedances in the arms are complex quantities of the form $Z = R + jX$; therefore, Eq. (39) represents a pair of equations in the real variables R and X:

$$R_a R_c - X_a X_c = R_b R_d - X_b X_d \tag{40a}$$
$$R_a X_c + R_c X_a = R_b X_d + R_d X_b \tag{40b}$$

Since the impedances making up the several arms of the bridge may be composed of various combinations of R, L, and C many variations of the Wheatstone bridge are used. Several of the more common forms together with the equations of balance are
